Visual Studio .NET

Microsoft Visual Studio.net	Microsoft® Visual Studio® .NET is the comprehensive tool set for rapidly building and integrating XML Web services, Microsoft Windows®–based applications, and Web solutions. Today, the world takes a little step into the future.

Check out the Visual Studio .NET Developer Center

You'll find in-depth content, community resources, downloads, product information, and more at this one-stop resource for Visual Studio .NET developers.

In This Library Section	Essentials
• **Documentation** • **Technical Articles** • **Introducing Visual Studio .NET** • **Developing with Visual Studio .NET** • **Visual Studio Walkthroughs** • **Code Samples**	• **Frequently Asked Questions About Visual Studio .NET** • **Inside the .NET Framework** • **Upgrading to .NET** • **Visual Studio .NET Support Center** • **Newsgroups** • **Communities**

Visual Basic and Visual C#

This section of the documentation discusses application development in Visual Basic or Visual C#. Either programming language can be used equally well in the subjects covered in this section. Applications made by either language are built on the services of the common language runtime and take advantage of the .NET Framework class library.

In This Section

Decision Chart
Provides an interactive guide to help you choose which approach or technology to use, as well as links to more information.
Walkthroughs in Visual Basic and Visual C#
Provides links to topics that walk you through complete scenarios covering different types of applications.
Common Tasks in Visual Basic and Visual C#
Provides links to topics on common programming tasks.
Code for Visual Basic Programmers
Highlights the code examples available within this section of the Visual Basic documentation.
Getting Started
Helps you begin working by listing what is new and by guiding you through version upgrading issues and application design decisions.
Upgrading Applications
Provides information about how to use programs created using previous versions of Visual Basic and Visual InterDev in Visual Basic .NET.
Managing Projects
Describes the project system for managing your applications as you write them.
Creating Applications
Discusses creating and configuring Windows applications, Web applications, and XML Web services, and helps you customize these applications for a global audience.
Accessing Data
Discusses aspects of incorporating data access functionality into your applications.
Programming with Components
Describes components of all kinds, including those you use on servers.
Programming with Office
Provides information on using Microsoft Office and Visual Studio .NET as part of your business application.
Reference
Contains links to several sections of reference information, including programming languages and user interface information.
Samples
Provides sample source code demonstrating how to program using Visual Basic and Visual C#.

Related Sections

Devenv Command Line Switches
Contains language reference topics that explain how to launch Visual Studio and build from the command prompt.
Error Messages
Contains error message topics for Visual Studio.
Automation and Extensibility Reference
Contains automation model language-reference topics for the integrated development environment (IDE), including debugging.
Language Equivalents
Compares keywords, data types, operators, and programmable objects (controls) for Visual Basic, C++, Visual C#, Java, JScript, and Visual FoxPro.
Class Library
Contains syntax and examples for the entire .NET Framework.
User Interface Reference
Contains topics for dialog boxes, windows, and other UI elements found in Visual Studio. Also covers shortcut keys.
Visual Studio Commands
Contains language-reference topics that explain how to use commands to interact with the IDE from the Command window and Find/Command box.
Visual Studio Walkthroughs
Contains topics discussing the steps involved in the development of specific applications types or major application features.
Getting Help from Microsoft Product Support Services
Describes various ways to get technical support.
Accessibility for People with Disabilities

Describes features that make Microsoft Visual Studio more accessible for people with disabilities.

Locating Readme Files

Gives you access to late-breaking notes on the product.

Visual Studio .NET

Links you to major starting points in the Visual Studio documentation.

Decision Chart

When designing your application, you may need help choosing between different technologies or approaches. This topic summarizes the choices and provides links to more information about rapid application development (RAD) with Visual Basic or C#. For more information about which language in Visual Studio to use, see Programming Languages.

Click the text for the option you are interested in; the node will expand to show the choices in that category.

What Do You Want to Do with Visual Basic or Visual C#?

Create a New Application

- **Application** - for help deciding between Windows Forms and Web Forms, see Windows Forms and Web Forms Recommendations
- **Control** - for more information, see Control Authoring for Windows Forms or Web User Controls and Web Custom Controls
- **Command-line application** - for details, see Console Application Template
- **Windows service** (formerly known as an "NT service") - a long-running Windows executable - for details, see Windows Service Applications
- **XML Web service** - XML Web services are applications that can exchange interoperable messages in a loosely coupled environment, using standard protocols such as HTTP, XML, XSD, SOAP and WSDL. XML Web services can be accessed from a Web application, a Windows desktop application, or another XML Web service - for details, see Programming the Web with XML Web Services
- **.NET component** - for details, see Component Authoring

For a step-by-step example, see Walkthrough: Creating a Distributed Application

For details, see Designing Distributed Applications

If you are targeting the browser on a cell phone, PDA (personal digital assistant), or pager, then use Mobile Web Forms - for details, see Creating ASP.NET Mobile Web Applications

Otherwise, use Web Forms - for details see Web Forms Pages

If you ...

- Are navigating between multiple, discrete tables of results ...
- Are manipulating data from multiple sources (for example, from different databases, from XML files, spreadsheets, and so on, all in the same dataset) ...
- Are exchanging data with other applications ...
- Are reusing the same set of rows and intend to cache them (for example, sorting, searching, and filtering cached results) ...
- Are doing a lot of processing per row ...
- Are manipulating the data using XML operations such as XML transforms or XPath ...
- Want ease of programming ...

Then use a dataset - for details, see ADO.NET Datasets

Otherwise, use direct access (data commands and data readers) - for details, see Performing Database Operations Directly.

For example, you would use data commands and data readers for:

- Performing DDL commands
- Performing updates or deletes based on a selection criteria
- Programmatically inserting records that are not based on user interaction
- Calling stored procedures to execute logic inside the server
- Retrieving scalar values from the database
- Processing a set of results in a forward only manner without updating and without caching the results
- Processing a set of results too large to fit in memory

For details, see Web Data Access Strategy Recommendations

For help deciding between the different types of server controls, see ASP.NET Server Controls Recommendations

- **Web server controls** - for details, see ASP.NET Server Controls by Function
- **HTML server controls** - for details, see ASP.NET Server Controls by Function (scroll down in the topic)
- **Create your own server control** - for details, see Web User Controls and Web Custom Controls

XML Web services are applications that can exchange interoperable messages in a loosely coupled environment, using standard protocols such as HTTP, XML, XSD, SOAP and WSDL. An XML Web service can be accessed from desktop applications (Windows Forms), Web applications, or other XML Web services. For details, see Programming the Web with XML Web Services

To send or receive a set of results to or from an XML Web service, use a dataset - for details, see ADO.NET Datasets

To access data within the logic of an XML Web service where that data is not being returned to the caller. . .

If you ...

- Are navigating between multiple, discrete tables of results...
- Are manipulating data from multiple sources (for example, from different databases, from XML files, spreadsheets, and so on, all in the same dataset) ...
- Are exchanging data with other applications ...
- Are reusing the same set of rows and intend to cache them (for example, sorting, searching, and filtering cached results) ...
- Are doing a lot of processing per row ...
- Are manipulating the data using XML operations such as XML transforms or XPath ...
- Want ease of programming ...

Then use a dataset - for details, see ADO.NET Datasets

Otherwise use direct access (data commands and data readers) - for details, see Performing Database Operations Directly.

For example, you would use data commands and data readers for:

- Performing DDL commands
- Performing updates or deletes based on a selection criteria
- Programmatically inserting records that are not based on user interaction
- Calling stored procedures to execute logic inside the server
- Retrieving scalar values from the database
- Processing a set of results in a forward only manner without updating and without caching the results
- Processing a set of results too large to fit in memory

Use Windows Forms - for details, see Creating Windows Applications

If you ...

- Are performing DDL commands ...
- Are calling stored procedures to execute logic inside the server ...
- Are retrieving scalar values from the database ...
- Are processing a set of results in a forward-only manner without displaying, updating, or caching the results ...
- Are processing a set of results too large to fit in memory ...

Then use direct access (data commands and data readers) - for details, see Performing Database Operations Directly

Otherwise, use a dataset - for details, see ADO.NET Datasets.

For example, you would use a dataset if you:

- Are binding results to a form to let the user view, insert, update, or delete records
- Are navigating between multiple tables of results
- Are manipulating data from multiple sources (for example, from different databases, from XML files, spreadsheets, and so on, all in the same dataset)
- Are exchanging data with other applications
- Are reusing the same set of rows (for example, sorting, searching, and filtering retrieved results)
- Are manipulating the data using XML operations such as XML transforms or XPath
- Want ease of programming

- Windows Forms controls - for help choosing between the different controls, see Windows Forms Controls by Function
- Inherit from an existing Windows Forms control (to expand its functionality), inherit directly from the control - for an example, see Walkthrough: Inheriting from a Windows Forms Control with Visual Basic .NET
- Custom controls - for details, see Control Authoring for Windows Forms

For details about working with Windows Forms controls (including securing applications, setting properties, handling events, anchoring controls, and so forth), see Windows Forms Controls

For help deciding which way to create a control, see Control Type Recommendations

For details, see Control Authoring for Windows Forms

- If you want to add to the functionality of an existing Windows Forms control, inherit directly from the Windows Forms control - for a step-by-step example, see Walkthrough: Inheriting from a Windows Forms Control with Visual Basic .NET or Walkthrough: Inheriting from a Windows Forms Control with Visual C#
- If you want to combine existing controls into a new control, inherit from the **UserControl** class - for details, see Inheriting from the UserControl Class
- If you want to create a control from scratch, inherit from the **Control** class - for details, see Inheriting from the Control Class

For details, see Web User Controls and Web Custom Controls

- **XML Web service**, which is technically not a component, but can be called from Windows applications, Web applications, or other XML Web services - for details, see Programming the Web with XML Web Services
- **.NET component** - for details, see Component Authoring

Create a console application - for details, see Console Application Template

Create a Windows service - for details, see Windows Service Applications

Access an Existing XML Web Service

For details, see Accessing XML Web Services in Managed Code

For a step-by-step example of accessing an XML Web service from a Windows application, see Walkthrough: Calling XML Web Services from Windows Forms

For a step-by-step example of accessing an XML Web service from a Windows application, see Walkthrough: Accessing an XML Web Service Using Visual Basic or Visual C#

Program with Objects and Components

For details, see .NET Framework Class Library in Visual Studio

Visual Basic - for details, see Object-Oriented Programming in Visual Basic

C# - for details, see new

Windows Forms Controls - for details, see Windows Forms Controls by Function

Web Forms server controls - for details, see ASP.NET Server Controls by Function

For help deciding between Web and HTML server controls, see ASP.NET Server Controls Recommendations

Web server controls - for details, see Controls You Can Use on Web Forms Pages

HTML server controls - for details, see HTML Server Controls

For help deciding between Web user controls and Web custom controls, see Recommendations for Web User Controls vs. Web Custom Controls

- **Web user control** - for details, see Introduction to Web User Controls
- **Web custom control** - for details, see Introduction to Web Custom Controls

- **Windows services** - for details, see Monitoring Windows Services
- **Processes** - use the Monitoring component - for details, see Monitoring and Managing Windows Processes
- **PerformanceCounter component** - for details, see Monitoring Performance Thresholds
- **EventLog component** - for details, see Logging Application, Server, and Security Events

- **File system** - for details, see Reacting to File System Events
- **Active Directory** - for details, see Creating Active Directory Components

Messaging component - for details, see Creating Messaging Components

- **On the server** - for details, see Creating Timer-Based Server Tasks
- **On the client** - for details, see Timer Component (Windows Forms)

For help deciding which way to create a control, see Control Type Recommendations

For details, see Control Authoring for Windows Forms

- If you want to add to the functionality of an existing Windows Forms control, inherit directly from the Windows Forms control - for an example, see Walkthrough: Inheriting from a Windows Forms Control with Visual Basic .NET
- If you want to combine existing controls into a new control, inherit from the **UserControl** class - for details, see Inheriting from the UserControl Class
- If you want to create a control from scratch, inherit from the **Control** class - for details, see Inheriting from the Control Class

For details, see Developing ASP.NET Server Controls

- **XML Web service**, which technically is not a component, but can be called from Windows applications, Web applications, or other XML Web services - for details, see Programming the Web with XML Web Services
- **.NET component** - for details, see Component Authoring

- **Expose your .NET component to COM** - for details, see Exposing .NET Framework Components to COM
- **Expose your COM component to the .NET Framework** - for details, see Exposing COM Components to the .NET Framework

Search the Web for controls and components created by third-party companies - try the Resource Center at the Got Dot Net Web site (http://www.gotdotnet.com)

Automate Tasks or Extend the Environment

For help deciding whether you need a macro, add-in, or wizard, see The Spectrum of Visual Studio .NET Automation

- **Macro** (Visual Basic only) - for details, see Automating Repetitive Actions by Using Macros
- **Add-in** - for details, see Creating an Add-in
- **Wizard** - for details, see Creating a Wizard

For details, see Introduction to Project Extensibility in Visual Basic and Visual C#

For advanced customization of the development environment, such as creating a new project type or a customized editor - see the " Visual Studio Integrator Program (VSIP)" section of The Spectrum of Visual Studio .NET Automation

Debug, Test, or Troubleshoot

For details, see Debugging Managed Code

For details, see Debugging XML Web Services in Managed Code

For details, see Introduction to Web Application Debugging

For details, see Debugging Preparation: Windows Applications

For details, see Debugging Preparation: Class Libraries

For details, see Debugging Windows Service Applications

For details, see Testing

Testing scalability - for details, see Testing for Scalability

For details, see Troubleshooting Problems Portal

Deploy

For help choosing which deployment project type to use, see Deployment Projects

For details, see Deployment of a Web Setup Project

For an example, see Walkthrough: Deploying a Web Solution

For details, see Deploying XML Web Services in Managed Code

For details, see Setup Projects

For an example, see Walkthrough: Deploying a Windows Application

If you are deploying a .NET component, create a merge module. For details, see Merge Module Projects. For a step-by-step example, see Walkthrough: Creating and Consuming a Merge Module.

If you are deploying an ActiveX control, create a CAB file. For details, see CAB File Projects. For a step-by-step example, see Walkthrough: Creating a CAB File.

Use dynamic properties - for details, see Introduction to Dynamic Properties

Upgrade from a Previous Version

For details, see Upgrading Applications Created in Previous Versions of Visual Basic

For details, see Upgrading Visual InterDev 6.0 Applications to Visual Studio .NET

Walkthroughs in Visual Basic and Visual C#

Walkthroughs give step-by-step instructions for common scenarios, which makes them a good place to start learning about the product or a particular feature area.

Walkthroughs are presented in the following areas:

• Distributed Applications Walkthrough • Data and XML Walkthroughs • XML Web Services Walkthroughs • Windows Application Walkthroughs • Web Walkthroughs • Visual Basic Language Walkthroughs • Deployment Walkthroughs	• Component and Control Authoring Walkthroughs • Dynamic Properties Walkthrough • Internationalization Walkthroughs • Accessibility Walkthroughs • Framework Services Component Walkthroughs • Upgrading Walkthrough • Office Development Walkthroughs

Note Some features listed in the walkthrough topics are not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

Distributed Applications Walkthrough

Creating a Distributed Application
Explains how to create a multitiered, distributed application that has both a Windows client and a browser interface.

Data and XML Walkthroughs

Simple Data Access in a Windows Form
Describes the basic steps required for accessing SQL Server data via a dataset in a read-write Windows Form.
Creating a Dataset with Tables, Keys, and One-to-Many Relationships
Describes the steps to create a dataset and use it to validate data in a one-to-many or keyed relationship.
Displaying Data in a Windows Form Using a Parameterized Query
Describes how to create a dataset containing only selected records, based on criteria that users provide at run time in a Windows Form.
Creating a Master-Detail Windows Form
Describes how to create a parent-child relationship in a dataset and display related records in a Windows Form.
Reading XML Data into a Dataset
Shows how to load XML data into a dataset, display it in a Windows Forms **DataGrid** control, and then display an XML schema for the file in a text box.
Mapping Data Source Tables to Dataset Tables
Describes how to load data from a database into a dataset based on a different schema using data adapter table and column mappings.
Handling a Concurrency Exception
Describes how to use the **DBConcurrencyException** object to identify concurrency exceptions and the actual record that caused the error.
Displaying Data in a Web Forms Page
Illustrates a basic data-access scenario, providing step-by-step instructions for how to create a Web Forms page that displays data in a grid control.
Creating Read-Only Data Access in a Web Forms Page
Describes how use an ADO.NET data command and data reader to provide optimized access to read-only data in a Web Forms page.
Updating Data Using a Database Update Query in Web Forms
Describes the basic techniques of creating a Web Forms page that uses a data command to update the database.
Using a DataGrid Web Control to Read and Write Data
Gives step-by-step details on how to use a grid control to allow users to view and edit data.
Creating Paged Data Access Using a Web Forms Page
Describes how to create a Web Forms page that allows users to view data records a few records at a time, paging back and forth to view earlier and later records.
Displaying an XML Document in a Web Forms Page using Transformations
Gives step-by-step details on how to read an XML file and display it in different ways on a Web Forms page.
Creating an XML File with an Associated XML Schema

Describes the steps for creating an XML file and a schema, associating the two, and working on the XML file in the designer's XML view.

Creating an XML Schema with the XML Designer

Describes the steps to create an XML purchase order schema as part of a Windows application.

XML Web Services Walkthroughs

Creating an XML Web Service Using Visual Basic or Visual C#

Explains how to create an XML Web service that converts temperatures measured in Fahrenheit to Celsius.

Accessing an XML Web Service Using Visual Basic or Visual C#

Describes how to make use of an existing XML Web service.

Calling XML Web Services from Windows Forms

Describes how to make calls to Web service methods from a Windows application.

Windows Application Walkthroughs

Creating a Simple Windows Form

Describes how to build and run a simple Windows Form.

Creating a Master-Detail Windows Form

Describes how to create a parent-child relationship in a dataset and display related records in a Windows Form.

Creating Dynamic Context Menus on Windows Forms

Steps through a detailed example of creating a single context menu to serve two or more different controls.

Switching Windows Forms Menu Structures Based on Application State

Gives directions for switching between **MainMenu** objects programmatically.

Demonstrating Visual Inheritance

Describes how to create a base Windows Form and compile it into a class library. You will import this class library into another project, and create a new form that inherits from the base form.

Creating a Multipane User Interface with Windows Forms

Describes how to create a multipane user interface that is similar to the one used in Microsoft Outlook.

Simple Data Access in a Windows Form

Describes the basic steps required for accessing SQL Server data via a dataset in a read-write Windows Form.

Displaying Data in a Windows Form Using a Parameterized Query

Describes how to create a dataset containing only selected records, based on criteria that users provide at run time in a Windows Form.

Calling XML Web Services from Windows Forms

Describes how to make calls to Web service methods from a Windows application.

Creating a Windows Service Application in the Component Designer

Describes how to create a long-running executable file that does not have a user interface.

Persisting an Object

Demonstrates how serialization can be used to persist an object's data between instances, allowing you to store values and retrieve them the next time the object is instantiated.

Retrieving Dialog Box Information Collectively Using Objects

Gives directions for using an object to expose a group of related data from a dialog box.

Updating Status-Bar Information at Run Time

Gives directions for programmatically controlling the data within status bar panels.

Web Walkthroughs

Creating a Basic Web Forms Page

Illustrates the basic techniques of how to create a Web Forms page in Visual Basic or Visual C#, add controls to it, and run it.

Creating a Web Application Using Visual C# or Visual Basic

Describes how to write a Web Forms application and then integrate a business-object component that gives you a 10% discount for purchases.

Creating a Web Application Using a Third-Party Business Object

Describes how to write a Web Forms application using Managed Extensions for C++ and then integrate a third-party business-object component that gives you a 10% discount for purchases.

Validating User Input in a Web Forms Page

Describes how to use Web Forms validation controls to check user entries without code, including required entries, data types, ranges, patterns, and specific values.

Displaying Data in a Web Forms Page

Illustrates a basic data-access scenario, providing step-by-step instructions for how to create a Web Forms page that displays data in a grid control.

Creating Read-Only Data Access in a Web Forms Page
Describes how use an ADO.NET data command and data reader to provide optimized access to read-only data in a Web Forms page.
Updating Data Using a Database Update Query in Web Forms
Describes the basic techniques of creating a Web Forms page that uses a data command to update the database.
Using a DataGrid Web Control to Read and Write Data
Gives step-by-step details on how to use a grid control to allow users to view and edit data.
Creating Paged Data Access using a Web Forms Page
Describes how to create a Web Forms page that allows users to view data records a few records at a time, paging back and forth to view earlier and later records.
Creating a Web User Control
Describes how to create a Web Forms user control — a page configured to act as a control — and use it on another page.
Converting a Web Forms Page to a User Control
Describes how to convert a basic Web Forms page into a user control that can be hosted on another page.
Creating a Web Custom Control
Describes how to create a custom control, add it to the toolbox, and use it on a Web Forms page.
Displaying an XML Document in a Web Forms Page using Transformations
Gives step-by-step details on how to read an XML file and display it in different ways on a Web Forms page.

Visual Basic Language Walkthroughs

Declaring and Raising Events
Illustrates how events are declared and raised in Visual Basic .NET.
Handling Events
Shows how to handle events using either the standard **WithEvents** keyword or the new **AddHandler/RemoveHandler** keywords.
Structured Exception Handling
Demonstrates how to create and maintain programs with comprehensive error handling, and how to use **Try...Catch...Finally**.
Defining Classes
Describes how to declare a class and its fields, properties, methods, and events.
Creating and Implementing Interfaces
Shows how interfaces are declared and implemented in Visual Basic .NET.
Multithreading
Shows how to create a multithreaded application that that searches a text file for occurrences of a word.
Calling Windows APIs
Explains how to use **Declare** statements and call Windows APIs. Includes information about using attributes to control marshaling for the API call and how to expose an API call as a method of a class.
Creating COM Objects with Visual Basic .NET
Demonstrates how to create COM objects with Visual Basic .NET, with or without the COM class template.
Implementing Inheritance with COM Objects
Demonstrates how to use Visual Basic 6.0 to create a COM object containing a class, and then use it as a base class in Visual Basic .NET.
Interacting with Files and Folders in Visual Basic .NET
Provides an introduction to the fundamentals of file I/O.
Manipulating Files Using .NET Framework Methods
Demonstrates how to read and write to a text file using the .NET Framework classes, Streamreader and Streamwriter.

Deployment Walkthroughs

Deploying a Web Solution
Guides you through deploying a Web application to a Web server.
Deploying a Windows Application
Guides you through deploying a Windows application to another computer.
Creating a CAB File
Guides you through distributing an ActiveX control.
Creating a Custom Action
Guides you through directing a user to a Web site following installation.
Passing Data to a Custom Action
Demonstrates passing data to a dynamic property during installation using a custom action and the **CustomActionData** property.
Using a Custom Action to Create a Database During Installation
Guides you through creating a custom action to create a database during installation.

Using a Custom Action to Pre-compile an Assembly During Installation
Guides you through creating a custom action to pre-compile an assembly after installation.
Creating and Consuming a Merge Module
Guides you through packaging a component in a merge module and then including the merge module in an installer.
Redirecting an Application to Target a Different XML Web Service During Installation
Demonstrates how to create a Web application that can be redirected to target a different XML Web service by using the URL Behavior property, an Installer class, and a Web Setup project.

Component and Control Authoring Walkthroughs

Authoring a Component with Visual Basic .NET
Shows the development of a simple component in Visual Basic, illustrating the interaction between client and component, object lifetime and circular references, debugging clients and components, and the use of shared methods and instance methods.
Authoring a Component with Visual C#
Shows the development of a simple component in Visual C#, illustrating the interaction between client and component, object lifetime and circular references, debugging clients and components, and the use of shared methods and instance methods.
Creating Your Own Collection Class
Shows how you can create your own collection classes by inheriting from one of the many .NET Framework collection classes and adding code to implement your own custom functionality.
Authoring a User Control with Visual Basic .NET
Shows the development of a simple control in Visual Basic that inherits from the **UserControl** class, and how to inherit from an established user control.
Authoring a User Control with Visual C#
Shows the development of a simple control in Visual C# that inherits from the **UserControl** class, and how to inherit from an established user control.
Inheriting from a Windows Forms Control with Visual Basic .NET
Shows the development of a simple control in Visual Basic that inherits from a pre-existing Windows Forms control.
Inheriting from a Windows Forms Control with Visual C#
Shows the development of a simple control in Visual C# that inherits from a pre-existing Windows Forms control.
Authoring a Simple Multithreaded Component with Visual Basic
Demonstrates the development of a simple multithreaded component in Visual Basic, explaining how threads work and how to coordinate multiple threads in your component.
Authoring a Simple Multithreaded Component with Visual C#
Demonstrates the development of a simple multithreaded component in Visual C#, explaining how threads work and how to coordinate multiple threads in your component.

Dynamic Properties Walkthrough

Storing and Retrieving Dynamic Properties
Describes the major steps in storing and retrieving property values.

Internationalization Walkthroughs

Localizing Web Forms Pages
Describes the major steps in creating a global-ready Web Forms application.
Localizing Windows Forms
Describes the major steps in creating a global-ready Windows Forms application.

Accessibility Walkthroughs

Creating an Accessible Web Application
Describes how to create an ASP.NET Web application that is optimized for different accessibility issues.
Creating an Accessible Windows Application
Describes how to create a Windows application that is optimized for different accessibility issues.

Framework Services Component Walkthroughs

Creating a Queue and Working with Messages
Describes how to use the **MessageQueue** component to interact with Windows message queues.
Creating a Message Queue Transaction with COM+ Services
Describes how to create a message queue transaction hosted by Enterprise Services (COM+ services).

Exploring Event Logs, Event Sources, and Entries

Describes how to use the **EventLog** component to interact with existing logs, create custom logs, and read and write values to logs.

Retrieving Categories and Counters

Describes how to use the **PerformanceCounter** component to retrieve lists of Windows performance counter categories on a server.

Changing and Retrieving Performance Counter Values

Describes how to use the **PerformanceCounter** component to retrieve and set raw and calculated values from a Windows performance counter.

Managing a Windows Process

Describes how to use the **Process** component to monitor and interact with Windows processes on a server.

Reacting to File System Events

Describes how to use the **FileSystemWatcher** component to monitor files and directories and react when changes occur.

Adding ActiveDirectory Objects

Describes how to use the **DirectorySearcher** component to interact with Active Directory file system structures.

Installing an Event Log Component

Describes how to use an installation component to configure server resources needed for your **EventLog** component instance.

Upgrading Walkthrough

Upgrading a Visual Basic 6.0 Application to Visual Basic .NET

Describes how to upgrade a standard application from Visual Basic 6.0 to Visual Basic .NET.

Office Development Walkthroughs

Programming with Office

Describes how to use Microsoft Office and Visual Studio .NET as part of your business application.

Samples and Walkthroughs | Common Tasks in Visual Basic and Visual C# | Visual Basic Code Example Topics

Common Tasks in Visual Basic and Visual C#

This topic is designed to help you quickly find the answers to your most frequent questions about programming in Visual Basic .NET. The following areas are represented in the list below:

• Projects • Windows Forms and Windows Applications • Web Forms and Web Applications • XML Web Services • Component Creation • Windows Services	• Data • XML • Server Components • Debugging • Deployment • Language (Visual Basic)

Note Some features listed in this topic are not available in the Standard Editions of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

Projects

How do I ...

- Upgrade my Visual Basic 6.0 project to Visual Basic .NET?
- Upgrade from J++ to C#?
- Create a new project?
- Reference a .NET or COM component?
- Reference an XML Web service?
- Add new files to my project?
- Adding existing files to my project?
- Add resources to my application?
- Make a copy of a project?

Windows Forms and Windows Applications

How do I ...

- Create a Windows application?
- Add a Windows Form to my application?
- Create a form that inherits from another Windows Form?
- Add controls to a Windows Form?
- Add controls at run time?
- Create a dynamic layout for my Windows Form?
- Choose the form to display when my application starts?
- Handle events on a Windows Form?
- Handle multiple events with the same procedure?
- Display message box prompts?
- Display modal dialog boxes?
- Add menus and menu items to my application?
- Create an MDI application?
- Draw lines and shapes?
- Create a Windows application in another language?
- Provide Help for my application?

Web Forms Pages and Web Applications

How do I ...

- Create a Web application?

- Add a Web Forms page to my application?
- Add controls to a Web Forms page?
- Add HTML controls to a Web Forms page?
- Handle events on a Web Forms page?
- Use styles to customize the appearance of my server controls?
- Reference controls on a Web Forms Page?
- Make sure that users fill in the required fields on my Web Forms page?
- Save Web Forms page values between round trips to the server?
- Create user controls and custom controls?
- View my Web Forms pages in a browser?
- Create a Web Forms page that will work with different browsers?
- Localize a form for different languages?
- Select an encoding for my Web pages?
- Secure my Web application?
- Protect against script exploits in my Web application?
- Display safe error messages?
- Use encoding to open and save files?
- Access SQL server as a local user?
- Access SQL server using Windows integrated security?

XML Web Services

How do I ...

- Create an XML Web service?
- Access an XML Web service so I can use it in my application?
- Add methods to my XML Web service?
- Publish my XML Web service so that others can find it?
- Secure my XML Web service?
- Handle and raise exceptions in XML Web services?

Component Creation

How do I ...

- Create a reusable library of classes?
- Create a Windows Forms user control in my project?
- Create a Windows Forms custom control in my project?
- Create a Web Forms user control in my project?
- Create a Web Forms custom control in my project?
- Use COM+ services for my class?

Windows Services

How do I ...

- Create a Windows service?
- Monitor the activities of an existing Windows service?
- Install a Windows service?
- Start a Windows service?

Data

How do I ...

- Decide which data access strategy to use?

- Create a connection to a database?
- Retrieve data from a database?
- Add new data to the data I have retrieved?
- Write changed data back to my database?
- Filter rows in my retrieved data?
- Update a database with the results of my work?
- Execute a command against a database?
- Check for and handle concurrency errors in my data?
- Bind to data in a Windows Form?
- Bind to data in Web Forms page?

XML

How do I ...

- Create an XML file?
- Validate an XML file?
- Create an XML schema?
- Transform XML on a Web Forms page?

Server Components

How do I ...

- Monitor changes to my file system?
- Monitor and control a Windows process?
- Use a timer?
- Read from and write to event logs?
- Create my own performance counters?
- Read from and write to performance counters?
- Create my own message queues?
- Read entries from a message queue?
- Send messages to a queue?

Debugging and Tracing

How do I ...

- Debug a Windows application?
- Debug a Web application?
- Debug an XML Web service?
- Debug a Windows service?
- Debug a class library or user control?
- Set breakpoints?
- Monitor the values of variables?
- Add tracing functionality to my application?
- Read from and write to event logs?

Deployment

How do I ...

- Work with multiple versions of the .NET Framework?
- Specify the runtime version for my application?
- Create a setup program for my application?
- Add a custom installer?

- Create a CAB file?
- Deploy my application over the Web?
- Make a property value configurable after deployment?

Language (Visual Basic)

How do I ...

- Declare a variable?
- Write an If condition?
- Write a For loop?
- Write a Case condition?
- Write a While loop?
- Enumerate a collection or array?
- Convert the type of a variable?
- Define and use an array?
- Define a class?
- Define a property?
- Define a method?
- Define an event?
- Pass an argument?
- Inherit from a class?
- Define a collection?
- Define and implement an interface?
- Define a user-defined type?
- Define a code module?
- Handle events?
- Handle exceptions?
- Perform string operations?
- Perform numeric calculations?
- Use custom attributes?
- Call a Win32 API?
- Read and write to files?
- Create a thread?
- Interact with COM components?
- Put comments in my code?
- Retrieve an embedded resource at run time?

Code for Visual Basic Programmers

There are many sources of code within the Visual Basic documentation set. This topic helps you get started in locating that code. Note that some of this code is contained within topics that provide further explanation or instructions on how to perform a task, whereas some is contained in special topics devoted only to displaying a code example.

Code in the Visual Basic Documentation

The following topics highlight useful code samples, by feature, within the Visual Basic documentation.

Code for Windows Forms Applications
: Lists code examples in the "Creating Windows Applications" section of the documentation.

Code for Windows Forms Controls
: Lists code examples in the "Windows Forms Controls" section of the documentation.

Code for Data Access
: Lists code examples in the "Accessing Data" section of the documentation.

Code for Web Applications
: Lists code examples in the "Creating Web Applications and Services" section of the documentation.

Code for Web Forms Controls
: Lists code examples in the "ASP.NET Server Controls" section of the documentation

Code for Component Programming
: Lists code examples in the "Programming with Components" section of the documentation.

Other Sources for Sample Code

You can also find sample code in the following locations:

Visual Basic Code Example Topics
: Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.

Visual Basic Language Tour
: Provides links to topics that contain code showing how to use basic language features, such as threading, inheritance, and file IO.

Visual Basic Sample Applications
: Lists compiled sample applications available to you in the documentation set.

Walkthroughs in Visual Basic and Visual C#
: Lists tutorial topics that provide step-by-step instructions on the process of creating applications and learning to use specific features.

Visual Basic QuickStarts and Other Samples
: Lists samples available to you when you install the .NET Framework SDK.

.NET Framework Reference Information
: Provides links to reference topics, some of which code examples of how to use classes and their members in.

Getting Started

This section of the documentation helps you get started with Visual Basic and Visual C# application development.

In This Section

Additional Resources for Visual Basic Programmers
Lists sites and newsgroups that can help you find answers to common Visual Basic problems.
Additional Resources for Visual C# Programmers
Lists sites and newsgroups that can help you find answers to common Visual C# problems.
What's New in Visual Basic and Visual C#
Covers new features for different areas, including Web development, data access, component creation, and the Visual Basic and Visual C# languages.
Visual Basic Standard Edition Features
Describes the features of the standard edition of Visual Basic.
Visual C# .NET Standard Edition
Provides links to descriptions of the features of the standard edition of Visual C#.

MSDN's Web site provides information on current third-party sites and newsgroups of interest. For the most current list of resources available, see the MSDN Community Web site (http://msdn.microsoft.com/vcsharp/community)).

On the Web

http://www.c-sharpcorner.com
Provides an online community for developers using C# to target the .NET Framework.
http://www.codeproject.com
Provides a community of Windows developers specializing in C# and .NET where source code, articles, and tutorials are shared.
http://www.codeguru.com/
Provides information about programming with C# and targeting the .NET Framework.

What's New in Visual Basic and Visual C#

Visual Basic and C# both have RAD (rapid-application development) support in Visual Studio .NET, with project templates, designers, and other features of the development environment. Both languages use the .NET Framework base classes.

In This Section

What's New in Web Development
Visual Basic and C# include support for Web Forms and XML Web services. Web Forms allow you to easily and quickly create the browser-based interface for ASP.NET Web applications. XML Web services allow you to package a Visual Basic or C# method and make it accessible on the Web.

What's New in Data
ADO.NET provides scalable, high-performance data access for all Visual Studio applications based on the .NET Framework. You can access data directly in the data source or create an in-memory cache — a dataset — for working with disconnected data. You can also work directly with XML as relational data or by creating and editing XML files directly.

What's New in Windows Forms and Controls
You can use Windows Forms and controls to create the presentation layer of a distributed application. Windows Forms provides a clear, object-oriented, extensible set of classes that enable you to develop rich Windows applications.

What's New in Projects
You can use the Project templates in this version to easily create various types of Windows and ASP.NET Web applications and controls. Project templates set necessary references for you, import namespaces, and add default items to your projects.

What's New in Components and Component Authoring
You can use nonvisual components and associated features to incorporate resources such as message queues, event logs, and performance counters into your applications. This version also offers RAD support for component creation via the Component Designer and framework classes that help you create controls and components.

What's New in Debugging
You can now debug projects that are part of the same solution but written in different languages, perform remote debugging, and implement trace functionality throughout your code to retrieve finely tuned output.

What's New in Extensibility and Automation
Visual Studio .NET includes a programmable object model that provides access to the underlying components and events of the integrated development environment (IDE). This model allows you to extend the functionality of the IDE, automate repetitive tasks, and integrate the IDE with other applications.

What's New in International Applications
Internationalization features in Visual Basic .NET make it easy to create applications targeting multiple locales, building on the globalization and localization features of the .NET Framework.

What's New in Upgrading
Visual Basic .NET 2003 now includes support for upgrading Visual Basic 6.0 WebClass and UserControl projects, plus a new tool for upgrading blocks of Visual Basic 6.0 code. Visual Studio .NET 2003 also includes the Java Language Conversion Assistant, which you can use to convert your Visual J++ 6.0 and Java-language projects to Visual C# .NET.

Related Sections

What's New in the Visual Basic Language
Visual Basic .NET, the next generation of the Visual Basic language, is designed to be a fast and easy way to create .NET applications, including XML Web services and ASP.NET Web applications.

Visual Basic .NET has many new and improved features such as inheritance, interfaces, and overloading that make it a powerful object-oriented programming language. Other new language features include free threading and structured exception handling. Visual Basic .NET fully integrates the .NET Framework and the Common Language Runtime, which together provide language interoperability, garbage collection, enhanced security, and improved versioning support.

Visual C# Language
Visual C# (pronounced C sharp) is a new programming language introduced in Visual Studio .NET. An evolution of C and C++, C# is simple, modern, type-safe, and object-oriented. It was designed for building a wide range of enterprise applications that run on the .NET Platform. Code that you write with Visual C# is compiled as managed code, which means it benefits from the services of the Common Language Runtime. These services include language interoperability, garbage collection, enhanced security, and improved versioning support.

Visual C# is fully supported within Visual Studio .NET by project templates, designers, property pages, code assistants, an object model, and other features of the development environment. The library for Visual C# programming is the .NET Framework.

What's New in Visual C# .NET 2003

Discusses the programmatic improvements in Visual C#, including enhancements to IntelliSense and the development environment.

What's New in Visual Studio .NET

Summarizes new features in the shared Visual Studio IDE used by Visual Basic, Visual C#, Visual C++, XML Web services, XML support, sample applications, and Help.

What's New in Deployment

Describes the new deployment features of Visual Studio .NET. Using the new deployment features you can distribute applications using Microsoft Windows Installer technology, deploy to production and staging servers, deploy tiers of your application to different test computers, and deploy ASP.NET Web applications to Web servers.

Inside the .NET Framework

Describes features of the .NET Framework, including the common language runtime, managed versus unmanaged execution, the common type system, and the .NET Framework class library.

What's New in Visual Studio Analyzer?

Describes the features of Visual Studio Analyzer, which analyzes the performance of distributed applications and performs debugging.

What's New in Visual Database Tools

Describes the Visual Database Tools, including the Database Designer, the SQL Editor, and Server Explorer. You can use these tools to help create and manage data-driven applications.

Introducing Visual J#

Provides an overview of the capabilities, features, and architecture of the Visual J# development system.

What's New in Web Development

An important new feature of Visual Studio is the ability to create Web applications — that is, Visual Basic and Visual C# applications that run on a Web server.

What's New in Visual Studio .NET 2003

In Visual Studio .NET 2003, there are small changes to Web Forms and the Web Forms Designer, all of which are designed to make Web Forms more robust and easier to develop.

Request Validation
By default, the page framework automatically scans posted user information for HTML elements, including tags and reserved characters. If it detects HTML, it raises an error. This provides protection against potentially malicious user input ("script injection"). For details, see Scripting Exploits.

Consolidated View and Build Commands
The **View in Browser** command (available when you right-click a Web Forms page in Solution Explorer) has been consolidated with the **Build and Browse** command. The **View in Browser** command now builds before displaying the page in a docked window in the designer. (Formerly it did not compile before displaying the page.) This change makes the **Build and Browse** command unnecessary, so that command has been removed from the shortcut menu.

Visual J# .NET Support
You can now develop Web Forms pages using Visual J# .NET. For more information, see Visual J# Overview.

Web References
The Start Browsing for XML Web Services pane in the Add Web Reference Dialog Box now provides Web links to both local and Internet sources of available XML Web services, including your own machine, UDDI (Universal Description, Discovery and Integration) servers on the local network, the Microsoft UDDI Business Registry, and the Test Microsoft UDDI Directory. For more information, see Locating XML Web Services and Adding and Removing Web References.

What's New in Visual Studio .NET 2002

The two major developments in Web applications are Web Forms and XML Web services:

- Web Forms technology allows you to quickly and easily create the user interface for ASP.NET Web applications. Web Forms pages represent a revolutionary improvement over existing Web-development tools, combining the speed and ease of a rapid application development (RAD) environment with the power of compiled programming languages. Web Forms output is compatible with any browser or mobile device and automatically renders the correct browser-compliant HTML for features such as styles, layout, and so on. For more information see Web Forms Pages.
- An XML Web service is a piece of business functionality — a component — that can be called by other components or applications via Internet protocols. XML Web services enable the exchange of data using standards like HTTP and XML messaging to move data across firewalls. XML Web services are not tied to a particular component technology or object-calling convention. As a result, programs written in any language, using any component model, and running on any operating system can access XML Web services. For more information see XML Web Services in Managed Code.

> **Visual Basic Note** If you are familiar with the Visual Basic language, see Language Changes in Visual Basic for a list of differences from previous versions.

RAD Support for Creating Web Forms Pages
Visual Studio includes a forms designer for creating HTML and ASP.NET-based forms. The designer allows you to drag HTML elements, controls, data classes, and other objects onto your form, use the Properties window to work with them, and use RAD techniques for adding code to them. For more details, see Creating and Managing Web Forms Pages.

RAD Support for Creating XML Web Services
Visual Studio includes a project template for creating XML Web services, in which you can expose methods for public access on the Web. You can create and distribute XML Web services using Visual Basic, Visual C#, or ATL server. For information, see Introduction to Programming XML Web Services in Managed Code.

RAD Support for Accessing XML Web Services
Visual Studio contains features that make it easy for you to locate existing XML Web services and make use of them in your applications. The Add Web Reference dialog box can be used to navigate services and add the necessary proxies to your project to access them. For details, see Accessing XML Web Services in Managed Code.

Programming Language Support
You can program Web Forms pages in any language supported in the .NET Framework, including Visual Basic .NET and Visual C# .NET. As in all .NET programming, you can create components in different languages; for example, you can create a Web Forms page in Visual Basic and call components written in Visual C#. For details, see Programming Languages.

Server Controls

When creating Web Forms pages, you use a special class of controls designed for use in browsers. The controls render as HTML, but execute code on the server, giving you maximum flexibility and power over the form. For details, see ASP.NET Server Controls.

Validation

You can create user input validation easily using a set of controls that automatically read user input, perform a validation check, and produce error information. For details, see Web Forms Validation.

Data Access in Web Applications

You can bind controls to a variety of data sources, ranging from simple arrays to datasets created in the ASP.NET Framework. The Web Forms Designer allows you to drag data objects onto the form and configure them. You can then bind any property of a Web Forms server control to any available data element. For more information, see Data Access in Web Forms Pages.

Compiling, Deploying, and Running Web Forms Pages

Web Forms pages are compiled into classes that are deployed as DLLs, giving you both performance and code security in your distributed application.

Debugging Web Applications

The Visual Studio .NET debugger is fully supported for XML Web services and for Web Forms pages. You can use the Visual Studio to debug your Web applications, including code that is running on a remote computer. For more information, see Introduction to Web Application Debugging.

Custom Web Control Creation

You can create your own Web server controls in two ways:

- **User Controls** You can create visual controls as Web Forms pages encapsulating the functionality you want, then embed those pages in other Web Forms pages. User Controls provide you with simple, easily developed controls that are ideal for components such as menus and toolbars. For more information, see Introduction to Web User Controls.
- **Custom server controls** Using an SDK provided with the .NET Framework, you can create your own controls that are fully integrated into the Visual Studio .NET environment. Developing custom controls allows you to create the design-time and run-time look of the control, specify property editors, set right-click behavior, and so on. For details, see Introduction to Web Custom Controls.

What's New in Visual Basic and Visual C# | What's New in Visual Studio .NET | What's New in the Visual Basic Language | C# Language Tour | What's New in Data

What's New in Data

ADO.NET is an evolutionary improvement to Microsoft ActiveX Data Objects (ADO). It represents a standards-based programming model that facilitates the development of distributed applications, especially Web applications. ADO.NET uses standards-based XML as a medium for data transfer, making it particularly appropriate for exchanging data between components and applications, even on unlike platforms.

Visual Basic Note If you are familiar with data access in Visual Basic 6.0, see Data Changes in Visual Basic .NET.

What's New in Visual Basic .NET 2003

Visual Basic .NET 2003 includes two new .NET Framework data providers and enhanced support for large XML Schemas.

.NET Framework Data Provider for ODBC

The .NET Framework Data Provider for ODBC provides optimized performance when working with ODBC data sources. For more information, see .NET Framework Data Providers.

.NET Framework Data Provider for Oracle

The .NET Framework Data Provider for Oracle provides optimized performance when working with Oracle databases. For more information, see .NET Framework Data Providers.

Improved Design-Time Experience for Working with Large XML Schemas

The XML Designer provides improved viewing options when working with schemas that contain many elements. A new zooming feature has been added that enables fine control over how schemas are viewed in the designer. The ability to expand and contract elements in a nested hierarchy has also been added to the designer. For more information, see XML Designer.

What's New in Visual Basic .NET 2002

Visual Basic .NET 2003 also includes the following features, which were introduced in Visual Basic .NET 2002.

Access Data Sources with High-Performance Data Components

ADO.NET provides high-performance .NET Framework data providers for direct access to databases and other data sources. Data providers give you precise control over SQL commands and stored procedures that can return data or scalar values or perform other database operations. Data reader objects provide an extremely fast way to return read-only data from a data source. For more information, see .NET Framework Data Providers.

Work with Disconnected Data

To make the most efficient use of database and server resources, you can create datasets that act as a relational cache for data drawn from a data source. (A data source is typically a database, but can also be XML or any source for which data providers are available.) You can define data adapters that fill the dataset and propagate dataset changes back to the data source using stored procedures or SQL statements. For more information about this new data model, see Introduction to Data Access with ADO.NET.

Create Datasets with Strongly Typed Access

With ADO.NET you can create a dataset based on an XML schema, producing a typed class in which tables and columns become first-class objects in the object model. Typed access makes code easier to read, is less error prone, and is fully supported by IntelliSense in the Visual Studio Code Editor. For more information, see Creating ADO.NET Typed DataSets from Schemas.

Exchange Data As XML With Other Applications or Components

You can serialize data into and out of XML streams that can be exchanged with other XML-enabled applications or components by using either the built-in features of datasets or XML-specific methods. ADO.NET can easily create XML Web services with methods that return datasets as XML. For more information, see Building XML Web Services Using ASP.NET.

Use Wizards for Configuring Data Access

Wizards can be used to create and configure data adapters and connections.

The Data Form Wizard helps you create a form that is bound to a dataset, creating type-appropriate data-bound controls. The Data Form Wizard can create simple forms bound to a single table or master-detail forms bound to related tables, and can display data one record at a time or in a data-bound grid. For more information, see Data Form Wizard and Creating Data Adapters Using a Wizard.

Add Data Components to a Form or Component by Dragging

Server Explorer greatly simplifies data configuration by providing the capability to drag and drop tables from existing data stores to create data adapters and connection objects. Adapters, connections, commands, data views, and dataset objects are all available for drag and drop operations from the **Data** tab of the Toolbox. For more information, see Data Tab, Toolbox.

Create XML Schemas

You can also use the Visual Studio .NET XML Designer to visually design XML Schemas, which are files that validate XML data as well as describe the structure of datasets. For more information, see Introduction to XML Schemas.

Edit XML Documents

XML can be edited in a code editor with IntelliSense, or by using a graphical user interface. XML documents can also be validated against any XML schema. For more information, see XML Files.

Bind Any Control Property to Data

Whether you are working with Windows Forms or Web Forms pages, you can bind any property — or multiple properties — of any control to data. For step-by-step examples, see Walkthrough: Displaying Data in a Web Forms Page and Walkthrough: Displaying Data in a Windows Form Using a Parameterized Query.

Work with Data Programmatically

The data classes provided in the .NET Framework are used to create and manipulate data and XML in code. For more information, see Data Namespaces in Visual Studio and XML Namespaces.

Work with ADO

ActiveX Data Objects (ADO) is still supported using the COM interoperability support in the .NET Framework. For more information, see COM Component Compatibility.

See Also

Accessing Data | What's New in Visual Basic and Visual C# | What's New in Visual Studio .NET

What's New in Windows Forms and Controls

Windows Forms is the new object-oriented framework that implements the .NET Framework. Windows Forms, in combination with the Windows Forms controls, provide a robust architecture for Windows application development in Visual Basic, C#, and Managed Extensions for C++.

> **Visual Basic Note** If you are familiar with forms in Visual Basic 6.0, see Forms Task Changes in Visual Basic .NET for an introduction to the new concepts.

What's New in Visual Studio .NET 2003

A number of additions have been made to Windows Forms in this release.

FolderBrowserDialog Component
The Windows Forms **FolderBrowserDialog** component is a modal dialog box that is used for creating, browsing, and selecting folders. For details, see FolderBrowserDialog Component (Windows Forms).

Security in Windows Forms
A fundamental aspect of programming is making sure your applications are secure. In Windows Forms, a great deal of work has been done to make this as easy as possible for developers. Nonetheless, there are important issues to be aware of. For details, see Windows Forms Security.

Nonrectangular Windows Forms
It is easy to customize the shape of Windows Forms. All that is required for nonrectangular forms is an image file and a few property settings. For details, see Creating Nonrectangular Windows Forms.

Windows Forms Designer for Managed Extensions for C++
Visual C++ introduces a rapid application development solution for creating your Windows Forms applications in Managed Extensions for C++. For details, see Managed Extensions for C++ Windows Applications.

Smart Device Programmability
Visual Basic .NET now allows you to develop rich applications for resource-constrained devices. You can use the tools provided by Visual Studio .NET and the .NET Compact Framework, a subset of the .NET Framework, to create, build, and debug applications that run on smart devices. For details, see Smart Device Projects.

While almost the entire Visual Basic language is supported for device development, certain Visual Basic .NET features were changed or dropped to accommodate for the inherent differences in device applications. For more information, see Developing Device vs. Desktop Applications.

What's New in Visual Studio .NET 2002

The following are all a part of client application development with Windows Forms.

Windows Forms
Windows Forms is the new platform for Microsoft Windows application development, based on the .NET Framework. This framework provides a basis for creating powerful applications. For details, see System.Windows.Forms Namespace. This framework provides a clear, object-oriented, extensible set of classes that enable you to develop rich Windows applications. For details, see Windows Forms.

Windows Forms as the Presentation Layer of a Three-Tier Application
Windows Forms can act as a user-interface layer within a three-tier application. Using HTTP calls to a server that is connected to a database, Windows Forms are capable of acting as the front end to a powerful, data-enabled architecture that leverages the rich user interface of a client application with the advanced processing of an application server. For details, see Walkthrough: Creating a Distributed Application.

Creating a Client Application
With Windows Forms, you are able to create a rich client application using C# or Visual Basic. This application can access a wide variety of data sources and provide data-display and data-editing facilities using Windows Forms controls. For details, see Walkthrough: Creating a Simple Windows Form and Walkthrough: Simple Data Access in a Windows Form.

Windows Forms and Web Forms
When designing applications that involve a user interface, you have two choices: Windows Forms and Web Forms. Both have full design-time support within the development environment and can provide a rich user interface and advanced application functionality to solve business problems. For a guide to deciding which technology is appropriate for a given application, see Windows Forms and Web Forms Recommendations.

Visual Basic Code Behind a Windows Form
When you select a Windows Application from the New Project dialog box, a solution is created with a Visual Basic project in it. This project contains references and one class, which is called Form1.vb. For details on the code in this class, see Anatomy of the Visual Basic Code Behind Windows Forms.

Windows Forms Security Model

Windows Forms security is based on the security policies established within the .NET Framework. The System.Security namespace provides the underlying structure of the .NET Framework security system, including base classes for permissions. Windows Forms Security addresses some of the concerns developers need to keep in mind as they create Windows applications.

Tag and Name Properties

The **Tag** and **Name** properties have been added to the Control Class. The **Tag** property is a repository within memory to store data about the control. The **Name** property contains the name of the control. The **Name** property can be used at run time to evaluate the object by name rather than type and programmatic name. For more information about the **Tag** property, see Control.Tag Property. For more information about the **Name** property, see Control.Name Property.

What's New in Components and Component Authoring | What's New in Visual Basic and Visual C# | What's New in Visual Studio .NET

What's New in Projects

Projects are the application building blocks for Visual Basic and Visual C# code. A finished application can be created with multiple projects of different languages.

> **Note** Some project types are not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

What's New in Visual Basic .NET 2003

Visual Basic .NET 2003 has added functionality for upgrading UserControl and WebClass projects from Visual Basic 6.0, plus support for multiple versions of the .NET Framework.

Upgrade Visual Basic 6.0 UserControl Projects
UserControl projects (also known as ActiveX Control projects) can be upgraded to a Windows Control Library. For more information, see UserControl Changes in Visual Basic .NET.

Upgrade Visual Basic 6.0 WebClass Projects
WebClass projects (also known as IIS Application projects) can be upgraded to an ASP.NET Web Application project. For more information, see WebClass Changes in Visual Basic .NET.

Target Multiple Versions of the .NET Framework
Applications can target a specific version of the .NET Framework. For more information, see Working With Multiple Versions of the .NET Framework.

What's New in Visual Basic .NET 2002

The following information highlights what has changed since version 6.0.

XML Web Services
XML Web services enable you to create server components that you can call from your applications using Internet-based protocols such as HTTP and XML. XML Web services can perform complex application logic and return data to a client. For more information, see Introduction to Programming XML Web Services in Managed Code.

Web Application Project
The Web Application template creates a new Web application by creating all necessary files on a specified Web server. For more information, see ASP.NET Web Application Template.

Windows Service Project
A Windows service application runs in the background of your system and requires no user interaction. It can perform functions such as performance monitoring. For more information, see Windows Service Template.

Console Application Project
The Console Application template creates an application that contains the necessary items needed to create applications that run from the command line. For more information, see Console Application Template.

Web Control Library Project
The Web Control Library template creates an application to author and publish Web controls. For more information, see Web Control Library Template.

Database Projects
The Database Project template is an application wizard that assists you in managing database elements such as tables and stored procedures. For more information, see Database Projects.

> **Note** This project type is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

Project Extensibility
Visual Studio .NET includes a programmable, project-neutral object model that provides access to the underlying components and events of the integrated development environment (IDE). For more information, see What's New in Extensibility and Automation.

Windows Forms and Controls
The new object-oriented Windows application structure is Windows Forms. Combined with Windows Forms Controls, Visual Studio .NET provides a design environment to quickly create standard Windows applications. For more information see What's New in Windows Forms and Controls.

Projects and Deployment
Visual Studio .NET includes deployment projects to assist in rapid deployment of your applications. The traditional deployment model has changed since Visual Studio 6.0. For more information see What's New in Deployment.

Upgrading from Visual Basic.6.0
The differences between Visual Basic 6.0 and Visual Basic .NET make it necessary to make changes when upgrading

applications. For more information, see Preparing a Visual Basic 6.0 Application for Upgrading.

Option Strict (Visual Basic Only)

The **Option Strict** statement disallows any data-type conversions in which data loss would occur and disallows any conversion between numeric types and strings. For more information, see Type Checking.

Creating New Web and Windows Projects in Existing Directories

Visual Studio .NET allows you to create new Web and Windows projects in existing folders with the New Project in Existing Folder template. For more information, see New Project in Existing Folder Template.

What's New in Visual Basic and Visual C# | What's New in Visual Studio .NET | What's New in the Visual Basic Language | Visual C# Language | Managing Projects | Programming with Office

What's New in Components and Component Authoring

You can easily create your own components in code or assemble them from the sophisticated components in the .NET Framework classes, using either Visual Basic or C#. You can use non-visual components and associated features to easily incorporate resources such as message queues, event logs, and performance counters into your applications.

The .NET Framework classes greatly expand the component programming capabilities of Visual Studio. Instead of a limited set of base classes, you have a large library of sophisticated components that you can use to assemble applications, or to derive high-quality components of your own.

> **Visual Basic Note** For an overview of how the Visual Basic language differs from previous versions, see Language Changes in Visual Basic.

What's New in Visual Basic .NET 2002

Visual Basic .NET 2003 includes the following features, which were introduced in Visual Basic .NET 2002.

Enhanced RAD Support for Creating Your Own Components
The new RAD (rapid application development) support makes authoring controls and non-visual components as easy as creating forms. Use inheritance to start from an existing component, and add other components to build in the functionality you need. For details, see Component Authoring.

Enhanced RAD Support for Creating Your Own Windows Controls
When you select the Windows Control Library project template, Visual Studio creates a **UserControl** class that inherits from **System.Windows.Forms.UserControl**. If you add a Custom Control item to your project, you will get a **CustomControl** class that inherits from **System.Windows.Forms.Control**. For details, see Control Authoring for Windows Forms.

Create Your Own Web Controls
Visual Studio provides a Web Control Library project template, which automatically creates a **WebControl** class that inherits from **System.Web.UI.WebControls.WebControl**. For details, see Developing ASP.NET Server Controls in the *.NET Framework Developer's Guide*.

.NET Framework Classes for Component Authoring
Inherit from the **Component** class or implement the **IComponent** interface to create your own component. For details, see Component Class, IComponent Interface and Component Model Namespaces in Visual Studio.

Messaging Components
You can create component instances that expose Microsoft Message Queuing functionality, allowing you to interact with message queues on local and remote computers. For details, see Creating Messaging Components.

System Monitoring Components
You can create instances of components that allow you to monitor and interact with a variety of system resources such as performance counters, event logs, services, and processes. For details, see Creating System Monitoring Components.

Timed Components
You can create server-based components that raise events on a recurring schedule or interval. For details, see Creating File System and Timer Components.

File System and Directory Components
You can create component instances that interact with file and directory structures, allow you to watch for and react to changes to a directory or file, or retrieve information about a system's directory structure. For details, see Creating File System and Timer Components.

Server Explorer
You can use the new Server Explorer tool to examine the resources that are available on servers to which you have network access, to verify the creation of resources you create, and to easily create components in your applications that reference existing resources. For details, see Introduction to Server Explorer

Common Language Runtime
The common language runtime is designed to simplify the creation and use of components. An important aspect of this simplification is enhanced interoperability between components written using different programming languages. For details, see Common Language Runtime.

Deploy Shared Components
You can create packages for sharing components that are used by multiple applications, eliminating versioning problems. For details, see Merge Module Projects.

What's New in Debugging

Visual Studio .NET provides a single integrated debugger for all Visual Studio languages, including Visual Basic and C#. A new, unified interface combines features of the Visual C++ and Visual Basic 6.0 debuggers, as well as many new features.

> **Visual Basic Note** If you are familiar with the debugger in Visual Basic 6.0, see Debugging Changes in Visual Basic .NET.

What's New in Visual Basic .NET 2002

Visual Basic .NET 2003 includes the following features, which were introduced in Visual Basic .NET 2002.

Cross-Language Debugging
Using the integrated debugger, you can debug projects that are part of the same solution but are written in different languages. For example, you can debug a solution that contains a project consisting of a Visual Basic or Visual C# user interface application and a Visual C++ server application, and you can step back and forth between these projects, for example from Managed Extensions for C++ to Visual Basic and back to Managed Extensions for C++. For more information, see Mixed-Mode Debugging.

Attaching to a Running Program
You can attach the debugger to a program that is already running and debug the program. Attaching to a running program works the same way whether the program is running on a host machine or a remote machine. The program does not need to be launched in the Visual Studio .NET integrated development environment (IDE). For more information, see Attaching to a Running Program or Multiple Programs.

Remote Debugging
You can attach to and debug a process that is running on a different computer from the one on which you are running Visual Studio. For example, if you are debugging a Windows Forms client application and an XML Web service it uses, you can run Visual Studio on the client and then attach to the server that is providing the XML Web service. You typically perform this kind of debugging for Web Forms projects or ASP.NET Web Service projects. For more information, see Attaching to a Running Program or Multiple Programs.

Debugging Multithreaded Applications
New for Visual Basic users is the ability to write and debug multithreaded applications. The Threads window can be used to view the threads that are running and to switch context. For more information, see Using the Threads Window.

Debugging Multiple Programs
You can debug multiple programs by attaching to running programs or by launching multiple programs from the Visual Studio IDE. For more information, see Debugging Multiple Programs.

Debugging ASP.NET Web Applications
Configuring debugging for ASP.NET Web applications has been significantly improved. In most cases you can simply choose Start from the Debug menu and the debugger will automatically attach to the ASP.NET worker process for debugging Web Forms, even if the ASP.NET worker process is running on a different server. Security configuration has been made easier by the addition of a debugger users group. For more information, see Debugging Script and Web Applications.

.NET Framework Classes for Debugging and Code Tracing
You can include instrumentation code in your Microsoft .NET application. Several .NET Framework classes are available for use both in debugging and in instrumenting your code. For more information, see Tracing and Instrumenting Applications in Visual Basic and Visual C#, Debug class, and Trace class, and scan the table of contents in the System.Diagnostics Namespace in the .NET Framework documentation.

Replacements for Visual Basic's Debug.Print
In Visual Basic .NET the **Debug.Print** method has been replaced by four new methods: Debug.Write method, Debug.WriteIf method, Debug.WriteLine method, and Debug.WriteLineIf method. The method most resembling **Debug.Print** is **Debug.Write**. To use these or any other methods of the **Debug** class, Visual Basic and Visual C# users should remember to include at the appropriate place in their code the statement `Imports System.Diagnostics` or `Using System.Diagnostics`, respectively. For more information, see Programming Element Support Changes Summary.

What's New in Visual Studio .NET | Debugging Managed Code | What's New in Visual Basic and Visual C#

What's New in Extensibility and Automation

Visual Studio .NET includes a programmable, project-neutral object model that provides access to the underlying components and events of the integrated development environment (IDE). This model has components that represent solutions, projects, tool windows, code editors, debuggers, code objects, documents, and events. You can extend the functionality of the IDE, automate repetitive tasks, and integrate other applications into the IDE. The object model can be used through four programming methods: macros, add-ins, wizards, and the Visual Studio .NET Integration Program (VSIP).

What's New in Visual Basic .NET 2002

Visual Basic .NET 2003 includes the following features, which were introduced in Visual Basic .NET 2002.

The Object Model for Extensibility of Visual Basic and Visual C# Projects

While Visual Studio .NET provides a general extensibility model, there is also an object model that is specific to Visual Basic and Visual C# projects. This language-specific model, contained in the **VSLangProj** namespace, allows you to programmatically manipulate project attributes found only in Visual Basic and Visual C# projects. These items include:

- VSProject Object Provides access to project properties.
- VSProjectItem Object Provides access to project item properties.
- Reference Object Provides access to a reference in a project.
- Imports Object Provides access to the project-level **Imports** statements for a Visual Basic project.
- BuildManager Object Provides support for implementing custom tools.
- Properties Property (Visual Basic and Visual C# Project Object) Contains the Visual Basic and Visual C# project properties.
- Properties Property (Visual Basic and Visual C# Configuration Object) Contains the Visual Basic and Visual C# configuration properties.
- Properties Property (Visual Basic and C# ProjectItem Object) Contains the properties of the individual files and folders contained in the project.

For more information on the general extensibility model, see Creating Add-Ins and Wizards. For more information on the Visual Basic and Visual C# extensibility model, see Introduction to Project Extensibility in Visual Basic and Visual C#.

Record Macros

You can automate repetitive tasks using the macro-recording features. The macros are stored as Visual Basic .NET procedures that may be edited using the Visual Studio .NET Macros IDE. This allows developers to edit the macro and even use macros to learn about the extensibility object model. For more information, see Automating Repetitive Actions by Using Macros.

Write Macros

For more complex situations, you can write macros using Visual Basic .NET. You can use all the features of Visual Basic .NET in macros, including inheritance, structured exception handling, and the .NET Framework. For more information, see Automating Repetitive Actions by Using Macros. You have programmatic access to macro projects, too. For more information, see The Macro Project Object Model.

Organize Macros

The Macro Explorer in the Visual Studio .NET Macros IDE provides a hierarchical view of the available macros, which are organized into modules contained in macro projects. From this window, you can organize, edit, and run macros. For more information, see Macro Explorer Window.

Manipulate Code without Parsing

The project-neutral extensibility model, called the general extensibility model, provides access to the individual code files of your project. You can navigate to and examine a specific class method or class variable without having to parse the code. Go straight to the code element you want to modify using the CodeModel Object, get its location in the Document Object, and examine and modify your code. For more information about using these models with Visual Basic and Visual C#, see Working with the CodeModel Object of a Visual Basic Application, and Working with the CodeModel Object of a Visual C# Application.

Add-ins

Add-ins are extensions to the IDE. They are compiled components that manipulate the environment and automate tasks. Add-ins can be invoked in a variety of ways, including the Add-in Manager, toolbar commands or buttons, the devenv command line, and events such as IDE startup. Add-in projects implement the IDTExtensibility2 interface. The power of add-ins rests in the fact that:

- You have access to all the features of .NET to modify the IDE.
- You can write add-ins using any of the programming languages included with Visual Studio.
- Add-ins are compiled, and therefore your code is not exposed as it is in macros.

The Add-In Wizard is provided to create skeleton add-in projects. For more information, see Creating an Add-In.

Wizards

Wizards are components that implement the IDTWizard interface. These applications lead users step-by-step to complete a task. For more information, see Creating a Wizard.

Visual Studio .NET Integration Program (VSIP)

Even more complex extensions to the IDE are possible through the VSIP. This program gives you access to additional objects and interfaces that let you create your own project types and designers. For more information, see The Spectrum of Visual Studio .NET Automation.

What's New in International Applications

Visual Studio .NET was designed from the start to make developing for an international audience easy by taking advantage of services built into the .NET Framework. In Visual Studio, there are two parts to creating an international-ready application. *Globalization* is the process of designing applications that can adapt to different cultures. *Localization* is the process of translating resources for a specific culture.

What's New in Visual Basic .NET 2002

Visual Basic .NET 2003 includes the following features, which were introduced in Visual Basic .NET 2002.

Cultures

A *culture* is composed of settings related to the user's language, environment, and cultural conventions. In applications that use the common language runtime and the .NET framework, culture takes the place of the National Language Support-based locale, which uses a system of LCID (Locale ID) codes. An LCID property of the CultureInfo class provides interoperability and eases integration with NLS-based software. There are two culture settings in Visual Studio: the UI culture setting determines which resources will be loaded, and the culture setting determines formatting of values such as dates, numbers, currency, and so on. For details, see Setting the Culture and UI Culture for Windows Forms Globalization or Setting the Culture and UI Culture for Web Forms Globalization.

XML Resource Files

Visual Studio resource files contain localized resources such as strings and images that are appropriate for particular cultures. For localization, you would typically create fallback resources for the culture where the application was originally developed and an additional resource file for each culture you wish to localize the application for. For details, see Introduction to International Applications in Visual Basic and Visual C#.

Main and Satellite Assemblies

When you build a project, the resource files are compiled and then embedded in satellite assemblies, or assemblies which contain only the localized resources. The fallback resources are built into the main assembly, which also contains the application code. For details, see Introduction to International Applications in Visual Basic and Visual C#.

Fallback System of Resources

Because the main assembly always contains the fallback resources, if a resource is not found in the localized satellite assembly, Visual Studio will attempt to load it in a hierarchical manner, eventually falling back to the resources in the main assembly. For details, see Hierarchical Organization of Resources for Localization.

Localization Project Support

Visual Studio provides project system support for editing and building localizable applications. The project system can create resource files for you, or you can manually create and edit them. For details, see Walkthrough: Localizing Windows Forms and Walkthrough: Localizing Web Forms Pages.

Full Unicode Support

Visual Studio resources are fully Unicode-based. The .NET Framework handles platform differences for you. It is no longer necessary to write separate code for different platforms such as Windows NT and Windows 98. For details, see Encoding and Windows Forms Globalization.

Support for International Web Applications

Visual Studio supports the development of globalized and localizable Web applications by providing resource management in Web applications, encoding Web pages in UTF-8, and allowing the layout of Web pages with relative sizing. For details, see Walkthrough: Localizing Web Forms Pages.

Deployment Localization

You can create localized setup projects in many languages. For details, see Deployment and Localization.

What's New in Upgrading

Visual Basic .NET 2003 includes several new features for upgrading Visual Basic 6.0 applications and code to Visual Basic .NET.

What's New in Visual Basic .NET 2003

Support for WebClass Upgrade
You can now upgrade Visual Basic 6.0 WebClass projects to ASP.NET Web Applications. For more information, see Upgrading WebClass Projects to Visual Basic .NET.

Support for UserControl Upgrade
You can now upgrade Visual Basic 6.0 UserControl projects to Visual Basic .NET Windows Control Libraries. For more information, see UserControl Changes in Visual Basic .NET.

Reuse Your Visual Basic 6.0 Code
There is a new tool that allows you to paste in blocks of Visual Basic 6.0 code and convert it to Visual Basic .NET. For more information, see Upgrading Visual Basic 6.0 Code with the Upgrade Visual Basic 6 Code Dialog Box.

Convert Visual J++ 6.0 and Java-Language Applications to Visual C# .NET
The Java Language Conversion Assistant allows you to convert Java-language and Visual J++ 6.0 applications to Visual C# .NET. For more information, see Java Language Conversion Assistant.

Visual Basic Standard Edition Features

This topic outlines and describes the features that are included in the Visual Basic .NET Standard Edition.

Platform Prerequisites

Before you can install Visual Basic .NET Standard Edition, the setup sequence automatically detects your system configuration and installs baseline components required by the product.

Baseline Components

Depending on your system configuration, one or more of the following baseline components is automatically installed on your computer:

- Microsoft Data Access Components 2.7
- Windows 2000 Service Pack 1

Common Language Runtime and Framework

The .NET Framework is a multi-language environment for building, deploying, and running applications and XML Web services. It consists of three parts:

- Common language runtime
- Unified programming classes
- ASP.NET

Languages and Libraries

Feature	Description
Visual Basic Compiler Options	Compiles Visual Basic source files within the Visual Studio integrated development environment (IDE) or from the command line using Vbc.exe. For more information on the Visual Basic .NET language and run-time library, see Visual Basic Language and Run-Time Reference.
C# Compiler Options	Compiles C# source files from the command line using Csc.exe. For more information, see Building from the Command Line.
C++ Compiler, Linker, and C++ Language	Compiles C++ source files from the command line using Cl.exe. For more information, see Building C++ Projects in Visual Studio.

Project and Editing Environments

Feature	Description
Visual Studio macros and programmability	The Visual Studio Macros development environment (separate from the Visual Studio environment) is used solely for creating, manipulating, editing, and running macros. For more information, see Macros Development Environment.
Visual Studio IDE add-ins	Extend the Visual Studio IDE by adding functionality that is not in the core product itself through COM add-ins. For more information, see Creating Add-Ins and Wizards.

Debugging

Feature	Description

Debugging Managed Code	Debugs Visual Basic and Visual C# and Visual Basic: • Windows applications • Class libraries • Windows control library • Web applications • Web Services • Console applications • Windows services Debugs Managed C/C++: • Applications • Class libraries • Web Services
Runtime Debugger (Cordbg.exe)	Helps tools vendors and application developers find and fix bugs in programs that target the .NET Framework common language runtime.

For more information, see Debug and Release Configurations.

Application Deployment

Feature	Description
Creating or Adding a Setup Project	Creates Windows Installer (.msi) files, which are used to distribute your application for installation on another computer or Web server.

Project Templates

The best way to create new projects is by using Visual Basic and Visual C# project templates, or application wizards. Project templates work in conjunction with application frameworks and libraries to create starter programs for you.

In the Standard Edition of Visual Basic, you do not have access to the empty project types and the project types that compile into DLLs. The following table lists the project types that are included.

Feature	Description
Introduction to Windows Applications	A project with the proper references and UI items to create a standard Windows-based application.
Introduction to ASP.NET Web Applications in Visual Studio	A project with the proper references and UI items to create an ASP.NET Web application.
Introduction to Programming XML Web Services in Managed Code	A project with the proper references and items to create a programmable XML Web service.
Console Application Template	A project with the proper references and items needed to create a project without a user interface that can be run from the command line.

For more information, see Visual Basic and Visual C# Projects. For a list of available project items, see File Types and File Extensions in Visual Basic and Visual C#.

Other Tools

The following designers are included in the Standard Edition.

Feature	Description
Web Forms Designer	Provides a set of visual tools for working with ASP.NET Web Forms pages and controls.
Windows Forms Designer	Provides a set of visual tools for working with Windows Forms and controls.
Component Designer	Provides a set of visual tools for working with nonvisual components.
XML Designer	Provides a set of visual tools for working with XML schemas, ADO.NET datasets, and XML documents.

Online Help and Documentation

Feature	Description

Visual Studio Combined Help Collection (VSCC)	Contains the standard Visual Studio documentation, as well as documentation for any installed third-party packages or add-ins.

Server Technologies

Feature	Description
Microsoft Data Engine (MSDE)	A fully SQL Server–compatible data engine used for building desktop and shared solutions that provide the easiest migration path to SQL Server 7.0. For more information, see http://www.microsoft.com/sql/msde/productinfo/features.asp.
Server Explorer	Provides access to data connections to MSDE or Access databases. For more information, see Introduction to Server Explorer.

Software Development Kits

Feature	Description
.NET Framework SDK	A wealth of resources — including DLLs, tools, and samples — that enable developers to build efficient, powerful, and scalable applications and services that take advantage of the new .NET Framework technology.

Visual C# .NET Standard Edition

Visual C# .NET Standard Edition is a member of the Visual Studio .NET family of development products. A Standard Edition is available for each programming language that targets the .NET Framework and is part of the Visual Studio suite.

In This Section

Visual C# Standard Edition Features
Take a look at Visual C# .NET Standard Edition Features.

Related Sections

Visual Studio .NET Editions
Provides more information on the various Visual Studio .NET products.
Visual Basic Standard Edition Features
Lists features included in Visual Basic .NET Standard Edition.
Visual C++ Standard Edition Features
Lists features included in Visual C++ .NET Standard Edition.
Visual Studio .NET Hardware Requirements
Make sure the Visual C# .NET Standard Edition is compatible with your current system configuration.

Visual C# Standard Edition Features

This topic outlines and describes the features that are included in the Visual C# .NET Standard Edition.

Platform Prerequisites

When you install Visual C# .NET Standard Edition, the setup sequence automatically detects your system configuration and then prompts you to install baseline components required by the product. This is Step 1 (Visual Studio .NET Prerequisites) of the four Visual Studio installation processes.

Baseline Components

Depending on your system configuration, one or more of the following baseline components are automatically installed on your machine:

- Windows 2000 Service Pack 3
- Microsoft Windows Installer 2.0
- Microsoft FrontPage 2000 Web Extensions Client
- Setup Runtime Files
- Microsoft Internet Explorer 6
- Microsoft Data Access Components 2.7
- Microsoft .NET Framework 1.1

Common Language Runtime and .NET Framework

The .NET Framework is a multilanguage environment for building, deploying, and running XML Web services and Web applications. It consists of three main parts:

- Common language runtime
- Unified programming classes
- ASP.NET

Languages and Libraries

The following language and library resources are available.

- C# compiler and runtime

  Compiles C# source files in the Visual Studio integrated development environment (IDE) or at the command line using CSC.EXE.

- C# environment language services, as follows:
  - Supports COM/platform code integration.
  - Includes garbage collection and type safety.
  - Provides security through intrinsic code trust mechanisms.
  - Supports XML Web-based components and extensible metadata concepts.
  - Provides interoperability with other languages, across platforms, and with legacy data.
  - Supports versioning to provide ease of administration and deployment.
  - Includes CodeSense.
- C++ compiler

  Compiles C++ source files from the command line using CL.EXE.

- Visual Basic compiler and runtime

  Compiles Visual Basic source from the command line using VBC.EXE.

Project and Editing Environments

The following project and editing environments are available.

- Visual C# Managed Project System

When compiling to managed code, the compiler translates your source code into Microsoft intermediate language (MSIL), a CPU-independent set of instructions that can be efficiently converted to native code.

- Visual Studio IDE add-ins

  Extend the Visual Studio IDE by adding functionality that is not in the core product itself through COM add-ins.

Debugging

The following topics provide debugging information for specific programming environments.

- Debugging Managed Code

  Provides information on managed debugging engines, which debug Managed Extensions for C++ applications, Windows applications, class libraries, and XML Web services.

- Debugging Visual C#

  Discusses debugging Visual C# Windows applications, class libraries, Windows control library, Web applications, XML Web services, console applications, and Windows services.

- Runtime Debugger

  Documents the .NET Framework SDK Debugger, which helps tools vendors and application developers find and fix bugs in programs that target the .NET Framework common language runtime.

For additional information, see Debug and Release Configurations.

Application Deployment

- Creating or Adding a Setup Project

  Discusses how to create Windows Installer (.msi) files, which are used to distribute your application for installation on another computer.

Application Wizards

The best way to create new projects is by using Visual C# application wizards. Visual C# application wizards work in conjunction with application frameworks and libraries to create starter programs for you that are modeled from project templates.

Application Wizard	Description
Windows Application	Creates a Visual C# application with a Windows user interface.
Class Library	Creates a project for creating classes that can be used in other a pplications.
Console Application	Creates a Visual C# application with a command-line interface.
ASP.NET Web Application	Creates a Visual C# application with a Web user interface.
ASP.NET Web Service	Creates an XML Web service with Visual C# that other applicatio ns can access.
ASP.NET Mobile Web Application	Creates an application viewable on PDAs, cellphones, and other mobile devices.
Empty Project	Creates an empty project for creating a local application.
Empty Web Project	Creates an empty project for creating a Web application.

Code Wizards and Items

After you create the framework of your project, you can use the Visual C# code wizards to help you add items such as classes, members, or functions into your programs. You can also add various files and items to your projects.

Solution Explorer Code Wizards

In Solution Explorer, use the **Add New Item** command. This opens the Add New Item dialog box, which is used to add an item to your project. When you select an item from the Categories list, the appropriate files and references are added to your project.

Note The **Add New Item Crystal Report** option is not included in the Visual C# Standard Edition.

Add New Item	Description

Windows Form	Adds a form for Windows applications to your project.
Class	An empty class declaration.
Component Class	A class for creating components using the visual designer.
Add User Control	Adds a class for creating a Windows Form control using the visual designer.
Data Form Wizard	Adds a .cs file for creating an XML schema with DataSet classes.
Data Set	Adds an .xsd file for creating an XML schema with DataSet classes.
XML File	Adds a blank .xml file.
XML Schema	Adds a file for creating a schema for XML documents.
Code File	Adds a blank .cs code file.
Custom Control	Adds a class for creating a user-drawn Windows Form control.
HTML Page	Adds an HTML page that can include client-side code.
Inherited Form	Adds a new form based on an existing Windows Form.
Web Custom Control	Adds a class for creating an ASP.NET server control.
Inherited User Control	Adds a new control based on an existing Windows Form control.
Windows Service	Adds a class for creating Windows services.
Text File	Adds a blank text file.
Frame Set	An HTML file that hosts multiple HTML pages.
XSLT File	Adds a file used to transform XML documents.
Style Sheet	Adds a cascading style sheet used for rich HTML style definitions.
Installer Class	Adds a class to be invoked at setup time.
Bitmap File	Adds a Win32 bitmap file.
Cursor File	Adds a Win32 cursor file.
Icon File	Adds a Win32 icon file.
Assembly Resource File	Adds a .NET resource file.
JScript File	Adds a script file containing JScript code.
VBScript File	Adds a script file containing VBScript code.
Windows Script Host	Adds a .WSF file containing script that is run as a Windows program.

Class View Code Wizards

In Class View, you can invoke the code wizards that have the new HTML interface. These wizards help you specify tokens when declaring programming elements such as classes, methods, and properties.

Code wizard	Description
C# Class Wizard	Adds an empty Visual C# class declaration to your project.
C# Method Wizard	Adds a method to your Visual C# class.
C# Property Wizard	Adds a property to your Visual C# class.
C# Field Wizard	Adds a field to your Visual C# class.
C# Indexer Wizard	Adds an indexer to your Visual C# class.
C# Interface Method Wizard	Adds a method to a C# interface.
C# Interface Property Wizard	Adds a property to a C# interface.
C# Interface Indexer Wizard	Adds an indexer to a C# interface.

For more information, see C# Code Wizards.

Other Tools

The following designers are available.

- Web Forms Designer

  Web Forms is an ASP.NET technology that you use to create programmable Web pages.

- Windows Forms Designer

Windows Forms is the new platform for Microsoft Windows application development, based on the .NET Framework. The Windows Forms Designer provides a rapid development solution for creating Windows applications.

- XML Designer

  The XML Designer provides a set of visual tools for working with XML schemas, ADO.NET datasets, and XML documents.

Online Help and Documentation

The Visual Studio Combined Help Collection (VSCC) contains the standard Visual Studio documentation, as well as documentation for any installed third-party packages or add-ins.

Server Technologies

Microsoft Data Engine (MSDE) is a fully SQL Server-compatible data engine used for building desktop and shared solutions that provide the easiest migration path to SQL Server 2000. For more information, see SQL Server 2000 Desktop Engine (MSDE 2000).

Software Development Kits

The .NET Framework SDK offers a wealth of resources — including DLLs, tools, and samples — that enable developers to build efficient, powerful, and scalable Web-based applications and services that take advantage of the new .NET Framework technology. For details, see .NET Framework SDK.

Upgrading from Visual Basic 6.0

Visual Basic .NET represents a departure from previous versions of Visual Basic in several ways. With a new development environment, an updated programming language, and a new forms package, moving from Visual Basic 6.0 to Visual Basic .NET may at first appear to be a daunting task.

In reality, much of what made Visual Basic distinctive has been retained and improved to make development easier than ever before. Although there are many changes, enhancements to the development environment and Help system ease the task of upgrading your code to conform with Visual Basic .NET and the .NET Platform. Extensive documentation is provided to help you make the transition, mapping your knowledge of Visual Basic 6.0 to Visual Basic .NET equivalents.

As you move forward to Visual Basic .NET, you will likely want to move some of your Visual Basic 6.0 projects forward, as well. Although there are differences between the two versions, tools are provided to ensure that your projects will be upgraded successfully.

The following documentation will help you to upgrade your applications and quickly get up to speed on the changes to Visual Basic.

Introduction to Visual Basic .NET for Visual Basic Veterans

As a veteran Visual Basic developer, you have undoubtedly invested a lot of time and effort in learning the intricacies of Visual Basic. At first glance, it may appear to you that Visual Basic .NET is so radically different from what you know that you will have to learn it all over again. In reality, while many things have changed, the overall experience of developing in Visual Basic remains essentially the same. Your knowledge of Visual Basic will help you immediately become productive in Visual Basic .NET.

There are, however, a number of changes to Visual Basic that will require you to adjust your mindset and set aside some old habits. Some of the rules for the language, tasks such as debugging and deployment, and even some terminology have changed — often in subtle ways. Ultimately, the changes make Visual Basic easier and more powerful than ever before.

The following topics will help you identify the changes in Visual Basic .NET from the perspective of a Visual Basic 6.0 veteran.

Covers new features for different areas, including Web development, data access, component creation, and the Visual Basic and Visual C# languages.

Integrated Development Environment Changes in Visual Basic .NET

Visual Basic .NET is fully integrated into the Visual Studio integrated development environment (IDE), which differs in several ways from the Visual Basic 6.0 IDE. The following sections describe the changes:

Window and Layout Changes

Menu Changes

Keyboard Mapping Changes

Window and Layout Changes

The standard arrangement of windows is different in Visual Basic .NET than it was in Visual Basic 6.0. If you prefer the Visual Basic 6.0 arrangement, you can set it by choosing **Visual Basic 6** from the **Window Layout** drop-down list on the **My Profile** tab of the Visual Studio **Start Page**.

In Visual Basic 6.0, the IDE was set to an MDI layout by default; you could optionally set it to SDI layout in the **Tools**, **Options** dialog box. In Visual Basic .NET, the default layout for the IDE is the new Tabbed documents layout; you can optionally set it to MDI layout in the **Tools**, **Options** dialog box.

In Visual Basic 6.0, you could control the docking behavior for some tool windows in the **Tools**, **Options** dialog box. In Visual Basic .NET, all windows are dockable by default; you can control their behavior via the **Dockable** command on the **Windows** menu.

There are also some differences in the available windows between Visual Basic 6.0 and Visual Basic .NET.

> **Note** In Visual Basic .NET, some of the debugging windows are only available in run mode; when you switch to design mode, the windows are hidden.

The following table shows some Visual Basic 6.0 windows and their Visual Basic .NET equivalents.

Visual Basic 6.0	**Visual Basic .NET**
Color Palette	No equivalent
Data View	No direct equivalent; replaced by **Server Explorer**
Form Layout	No equivalent
Immediate	**Command Window**
Project Explorer	**Solution Explorer**
Watches	**Watch 1**, **Watch 2**, **Watch 3**, **Watch 4**

Menu Changes

Menu commands in Visual Studio .NET are standardized for all languages; in some cases, Visual Basic 6.0 menu commands are replaced by different commands in Visual Studio .NET.

In Visual Basic 6.0, all menu commands were visible at all times but were grayed-out when out of context; in Visual Basic .NET, the set of available commands differs according to context.

The following table lists some common Visual Basic 6.0 commands and their Visual Basic .NET equivalents.

Visual Basic 6.0	**Visual Basic .NET**
Add-Ins, **Add-In Manager**	**Tools**, **Add-in Manager**
Debug, **Add Watch**	**Add Watch** (context menu only)
Debug, **Edit Watch**	No equivalent. Watches are edited in the Watch window.
Debug, **Run To Cursor**	**Run To Cursor** (context menu only)
Debug, **Set Next Statement**	**Set Next Statement** (context menu only)
Debug, **Show Next Statement**	**Show Next Statement** (context menu only)
Debug, **Toggle Breakpoint**	**Disable Breakpoint** or **Breakpoint** (context menu only)
Edit, **Complete Word**	**Edit**, **Intellisense**, **Complete Word**

Edit, **Find**	**Edit**, **Find and Replace**
Edit, **Find Next**	**Edit**, **Find and Replace**
Edit, **Indent**	**Edit**, **Advanced**, **Increase Line Indent**
Edit, **Insert File**	**Edit**, **Insert File As Text**
Edit, **List Constants**	**Edit**, **Intellisense**, **List Members**
Edit, **List Properties/Methods**	**Edit**, **Intellisense**, **List Members**
Edit, **Outdent**	**Edit**, **Advanced**, **Decrease Line Indent**
Edit, **Parameter Info**	**Edit**, **Intellisense**, **Parameter Info**
Edit, **Quick Info**	**Edit**, **Intellisense**, **Quick Info**
Edit, **Replace**	**Edit**, **Find and Replace**
File, **Make *ProjectName***	**Build**, **Build *ProjectName***
File, **Make Project Group**	**Build**, **Build Solution**
File, **Print Setup**	**File**, **Page Setup**
File, **Recent files list**	**File**, **Recent Projects**
File, **Remove Project**	**Edit**, **Remove**
File, **Save Project Group**	**File**, **Save *SolutionName*** or **File**, **Save All**
File, **Save Project Group As**	**File**, **Save *SolutionName* As**
File, **Save Selection**	**File**, **Save Selected Items**
Format, **Size to Grid**	No equivalent. Controlled by **Snap to Grid** environment option.
Help, **Microsoft on the Web**	**Help**, **Show Start Page**
Project, **Add Class Module**	**Project**, **Add Class**
Project, **Add Data Environment**	No equivalent. Data Environment is not supported.
Project, **Add Data Report**	No equivalent. Data Reports are not supported.
Project, **Add DHTML Page**	No equivalent. DHTML Pages are not supported.
Project, **Add File**	**Project**, **Add New Item** or **Project**, **Add Existing Item** **Note** In Visual Basic 6.0 the file itself was added to the project; in Visual Basic .NET a copy of the file is added.
Project, **Add Form**	**Project**, **Add Windows Form** or **Project**, **Add Inherited Form**
Project, **Add MDI Form**	**Project**, **Add Windows Form** or **Project**, **Add Inherited Form**
Project, **Add Property Page**	No equivalent. Property Pages are not supported.
Project, **Add User Document**	No equivalent. ActiveX Documents are not supported.
Project, **Add Web Class**	No equivalent. Web Classes are not supported.
Project, **Components**	No equivalent. Components are managed in the Toolbox.
Project, **References**	No equivalent. References are managed in Solution Explorer.
Project, **Remove *item***	**Edit**, **Delete** **Note** **Remove** removed the item from the project but not from disk; **Delete** deletes the item.
Run, **Break**	**Debug**, **Break All**
Run, **End**	**Debug**, **Stop Debugging**
Run, **Restart**	**Debug**, **Restart**
Run, **Start**	**Debug**, **Start**
Run, **Start With Full Compile**	**Debug**, **Start Without Debugging**
Tools, **Add Procedure**	No equivalent. Procedures are added in the Code Editor.
Tools, **Menu Editor**	No equivalent. The Menu Editor is replaced by the **MainMenu** and **ContextMenu** components.

Tools, **Procedure Attributes**	No equivalent.
Tools, **SourceSafe**	**File**, **Source Control**
View, **Call Stack**	**Debug**, **Windows**, **Call Stack**
View, **Color Palette**	No equivalent. There is no Color Palette window.
View, **Data View Window**	No equivalent. There is no Data View window.
View, **Definition**	**Go To Definition** (context menu only)
View, **Form Layout Window**	No equivalent. There is no Form Layout window.
View, **Immediate Window**	**Debug**, **Windows**, **Immediate**
View, **Last Position**	No equivalent. Use Bookmarks.
View, **Locals Window**	**Debug**, **Windows**, **Locals**
View, **Object**	**View**, **Designer**
View, **Object Browser**	**View**, **Other Windows**, **Object Browser**
View, **Project Explorer**	**View**, **Solution Explorer**
View, **Watch Window**	**Debug**, **Windows**, **Watch**
Window, **Arrange Icons**	No equivalent.
Window, **Cascade**	Only available in MDI layout mode.
Window, **Tile Horizontally**	Only available in MDI layout mode.
Window, **Tile Vertically**	Only available in MDI layout mode.
Window, Window list	**Windows...**

Keyboard Mapping Changes

Keyboard mappings in Visual Studio .NET are standardized so that you can use the same keyboard shortcuts for all languages and tools. The result is that some of the familiar Visual Basic 6.0 keyboard shortcuts now invoke different functions. For example, in Visual Basic 6.0, F8 was the keyboard shortcut for Step Into when debugging; in Visual Basic .NET, F8 is the shortcut for Go to Next Location in the Code Editor.

If you prefer the Visual Basic 6.0 keyboard mappings, you can set them by choosing **Visual Basic 6** from the **Keyboard Scheme** drop-down list on the **My Profile** tab of the Visual Studio **Start Page**.

Project Changes in Visual Basic .NET

Projects in Visual Basic .NET are similar to projects in Visual Basic 6.0; however, there are some differences that you should be aware of.

In Visual Basic 6.0, projects used a reference-based model — the project file contained references to project items specifying their path. For example, when you added a text file to a project, the project file pointed to the location of the file; when the project was built, the text file would be loaded from that location.

Visual Basic .NET uses a folder-based model — all project items are placed in the project folder hierarchy. When you add a text file, a copy of the file is placed in the project folder; when the project is built, the text file is loaded from that copy of the file.

In Visual Basic 6.0, the **Remove** command removed an item from a project, but the file still remained on disk. In Visual Basic .NET, the **Remove** command is replaced by a **Delete** command, which both removes and deletes the file. The **Exclude From Project** command can be used to exclude a file from a project without deleting it.

In Visual Basic 6.0, multiple projects could be added in the Project Explorer; multiple projects were called Project Groups. In Visual Basic .NET, Solution Explorer replaces the Project Explorer; Project Groups are replaced by solutions. Where Project Groups could only contain Visual Basic projects, solutions can contain projects created in any combination of Visual Studio .NET languages.

In Visual Basic 6.0, project files (.vbp) and project group files (.vbg) were text files that could be edited directly in a text editor. In Visual Basic .NET, project and solution files are in an XML format; they should not be edited directly.

Describes differences between Visual Basic 6.0 and Visual Basic .NET.

Project Property Changes in Visual Basic .NET

Project properties in both Visual Basic 6.0 and Visual Basic .NET specify various global settings for a project. In Visual Basic 6.0, project properties were set in the Project Properties dialog box. In Visual Basic .NET, project properties are set in the Property Pages dialog box; some properties can be set on a per-configuration basis.

Many of the project properties differ between Visual Basic 6.0 and Visual Basic .NET. The following list provides a comparison of Visual Basic 6.0 and Visual Basic .NET project properties. Note that not all properties are available for all project types.

Visual Basic 6.0	**Visual Basic .NET**
Command Line Arguments	**Command line arguments** (configuration dependent)
Compile options	No equivalent. For more information, see Visual Basic Compiler Options.
Conditional Compilation Arguments	**Conditional Compilation Constants — Custom Constants**
DLL Base Address	**DLL base address**
Help File Name	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
Icon	**Application icon**
Project Description	No equivalent. Version information for assemblies is stored in the AssemblyInfo.vb file.
Project Help Context ID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
Project Name	No equivalent. Replaced by **Assembly name** and **Root namespace**.
Project Type	**Output type**
Remote Server	No equivalent.
Remove information about Unused ActiveX Controls	No equivalent.
Require License Key	No equivalent.
Retained In Memory	No equivalent. This property was related to MTS components, which are not supported in Visual Basic .NET.
Start Mode	No equivalent.
Startup Object	**Startup object**
Threading Model	No equivalent. Visual Basic .NET supports multithreading.
Title	No equivalent. Version information for assemblies is stored in the AssemblyInfo.vb file.
Unattended Execution	No equivalent.
Upgrade ActiveX Controls	No equivalent.
Use existing browser	No equivalent.
Version Compatibility	No equivalent. Visual Basic .NET assemblies eliminate the need for binary compatibility settings.
Version Information	No equivalent. Version information for assemblies is stored in the AssemblyInfo.vb file.
Version Number	No equivalent. Version information for assemblies is stored in the AssemblyInfo.vb file.
When this project starts	**Start Action**

Project Type Changes in Visual Basic .NET

The types of projects that can be created with Visual Basic .NET differ from Visual Basic 6.0. In some cases, the project types are essentially the same but the names have changed; in other cases some Visual Basic 6.0 project types have no direct equivalent.

The following list provides a comparison of Visual Basic 6.0 and Visual Basic .NET project types.

Visual Basic 6.0	**Visual Basic .NET**
Standard EXE	Windows Application
ActiveX DLL	Class Library
ActiveX EXE	Class Library
ActiveX Control	Windows Control Library
ActiveX Document	No equivalent. Visual Basic .NET can interoperate with ActiveX Documents.
DHTML Application	No equivalent. Use ASP.NET Web Application.
IIS Application (Web Class)	No equivalent. Use ASP.NET Web Application.

Visual Basic and Visual C# Projects | Web Changes in Visual Basic .NET | Project Changes in Visual Basic .NET

Reference Changes in Visual Basic .NET

In Visual Basic 6.0, project references to type libraries were managed in the References dialog box. Once a reference was added, you could access the object in code.

In Visual Basic .NET, references are made to assemblies and are added and removed in the project's References node in Solution Explorer. References can also be made to COM components. Project-to-project references and Web references to XML Web services are also supported.

In Visual Basic 6.0, controls were added to a project in the Components dialog box. Once added, they were visible in the Toolbox.

In Visual Basic .NET, controls are added to the Toolbox in the Customize Toolbox dialog box.

Referencing Namespaces and Components | Project Changes in Visual Basic .NET

Web Changes in Visual Basic .NET

Visual Basic 6.0 included several features that supported programming for the Web: Internet Information Services (IIS) applications (Web classes), DHTML applications, ActiveX documents, and ActiveX controls that could be downloaded to Web pages.

Visual Basic .NET was built from the ground up to support Web programming with features such as ASP.NET Web applications, XML Web services, and much more. Because Visual Basic .NET is built on a new architecture, Visual Basic 6.0 Web features either are no longer supported or have changed substantially; however, your knowledge of Web programming should help you to quickly transition to the Web technologies in Visual Basic .NET.

In Visual Basic 6.0, IIS applications used the Active Server Pages (ASP) model to create applications that ran on Internet Information Services. In Visual Basic .NET, ASP.NET technology allows you to create the application using Web Forms pages, and to create components using XML Web services. These technologies make programming for the Web very similar to programming for Windows in Visual Basic 6.0. For more information, see Introduction to ASP.NET Web Applications in Visual Studio.

Visual Basic 6.0 DHTML applications used the Dynamic HTML object model and Visual Basic code to create applications that could respond to actions performed by the user in a browser. Visual Basic .NET Web Forms expand upon the DHTML model, providing richer dynamic user-interface capabilities as well as client-side validation.

Visual Basic 6.0 ActiveX documents are not supported in Visual Basic .NET. You can still interoperate with ActiveX documents from your Visual Basic .NET Web applications, but development should be maintained in Visual Basic 6.0.

Visual Basic .NET also allows you to create ActiveX controls that can be downloaded to Web pages, or to use existing ActiveX controls in your Visual Basic .NET applications.

WebClass Changes in Visual Basic .NET

In Visual Basic 6.0, WebClass projects (also known as IIS Application projects) were used to create Web applications based on Active Server Page (ASP) technology.

In Visual Basic .NET, ASP.NET Web Application projects are used to create Web applications based on the newer ASP.NET technology. When a Visual Basic 6.0 WebClass project is upgraded to Visual Basic .NET, it is converted to an ASP.NET Web Application project.

In Visual Basic 6.0, WebClass projects had a **StateManagement** property that could be used to keep an instance of the webclass alive between requests. This was done by setting the **StateManagement** property to **2 – wcRetainInstance** at design time; there was also a **ReleaseInstance** method that could be used to terminate an instance.

In Visual Basic .NET, ASP.NET Web applications do not have a **StateManagement** property; the model for managing application state differs considerably. Any code related to state management will need to be replaced. For more information, see Web Forms State Management.

Function and **Sub** procedures in your Visual Basic 6.0 code (for example, **ProcessTags** or **Respond**) will have their scope changed from **Private** to **Public** to allow the WebClass Compatibility runtime to execute them.

Certain Visual Basic 6.0 WebClass events are not supported in ASP.NET (for example, **Initialize**, **BeginRequest**, **EndRequest**, and **Terminate**). These event procedures will be upgraded but will not be called at runtime. After upgrading, you will need to move any code in these events to equivalent ASP.NET events.

Declarations will be added to your project: one for the WebClass and one for each of the WebItems and Templates in the WebClass project. A **Page_Load** event procedure will be added to the project, creating first a WebClass object and then WebItem objects for each of the WebItems and Templates associated with the Visual Basic 6.0 WebClass project. Finally, in the **Page_Load** event procedure, you will see a call to the WebClass Compatibility runtime: **WebClass.ProcessEvents**. This allows the runtime to render the WebItem specified in the Request URL. This code is the only new code added to your upgraded project and only serves to emulate the underlying behavior of the Visual Basic 6.0 WebClass runtime.

> **Note** There are a number of behavioral differences for properties, methods, and events between ASP and ASP.NET objects. Before upgrading a WebClass to ASP.NET, you should understand these differences so you know how to modify your code. For more information, see Migrating to Web Forms.

Data Changes in Visual Basic .NET

In Visual Basic 6.0, data access was accomplished using ActiveX Data Objects (ADO). In Visual Basic .NET, data access is accomplished using ADO.NET, which is a part of the .NET Framework. There are a number of differences both conceptually and in terms of tasks between the two technologies. For more information on conceptual differences between ADO and ADO.NET, see Comparison of ADO.NET and ADO.

> **Note** Visual Basic 6.0 also provided backward compatibility support for Remote Data Objects (RDO) and Data Access Objects (DAO). These technologies are supported in Visual Basic .NET only as COM objects; applications that use RDO or DAO data binding cannot be upgraded to Visual Basic .NET. For more information, see Upgrading Applications Created in Previous Versions of Visual Basic.

In Visual Basic 6.0, there were two common methods of implementing data access in an application: at design time by binding to an ADODC control or by using a Data Environment, or at run time by creating and interacting with recordset objects programmatically. In Visual Basic .NET, there are two analogous methods of implementing data access: at design time by using data adapters and datasets, or at run time by adding code to create data adapters and datasets programmatically. For more information, see Creating Data Adapters and ADO.NET Datasets.

In Visual Basic 6.0, data binding was accomplished by setting the binding-related properties of a control: **DataChanged**, **DataField**, **DataFormat**, **DataMember**, and **DataSource**. In most cases, the display property of a control (for example, the Text property of a **TextBox** control) was bound to a field in a data source.

In Visual Basic .NET, data binding has a much broader definition — you can bind any property of any control to any structure that contains data. Binding in Windows Forms is accomplished via a **DataBindings** property that contains a collection of **Binding** objects for the control. For more information, see Data Binding and Windows Forms.

> **Note** ADO data binding is supported for backward compatibility via the Microsoft Visual Basic .NET Compatibility Data Runtime.

In Visual Basic 6.0, data-bound forms were automatically created by dragging database elements from a Data Environment onto a form.

In Visual Basic .NET, you automatically create data-bound forms by running the Data Form Wizard. For more information, see Data Form Wizard.

In addition to support for ADO.NET, Visual Basic .NET also provides support for direct programmatic access to databases using data commands. For more information, see Performing Database Operations Directly.

Component Authoring Changes in Visual Basic .NET

Although both Visual Basic 6.0 and Visual Basic .NET provide capabilities for creating components, there are some significant differences in component authoring. In Visual Basic 6.0, component authoring was all about creating COM components: ActiveX Controls, ActiveX DLLs, and ActiveX EXEs that could be used in COM applications.

In Visual Basic .NET, components are based on the .NET Framework; you create components that can be used in applications built using the .NET Framework. Components built with Visual Basic .NET are based on inheritance — every component derives from either the **Component** or **Control** base class. For more information, see Component Classes.

Visual Basic 6.0 provided two models for threading — components could be either single threaded or apartment threaded. Visual Basic .NET supports true multithreaded components. For more information, see Multithreading in Components.

In Visual Basic 6.0, the **Instancing** property of a class controlled the access level and the way a component could be created. In Visual Basic .NET, setting the access modifier and access level in the constructor for a component class controls instancing. For more information, see Component Instancing Changes in Visual Basic.

Binary compatibility for components was important in Visual Basic 6.0 in order to prevent version conflicts; it was controlled by the **Version Compatibility** property for the component project. In Visual Basic .NET, versioning is built into the assemblies for components; you no longer need to worry about setting binary compatibility. For more information, see Components and Assemblies.

In Visual Basic 6.0, you could create ActiveX controls (also referred to as user controls) that could be used in Windows applications. In Visual Basic .NET, you can create user controls for Windows Forms, or you can inherit from existing controls to add functionality. For more information, see Control Authoring for Windows Forms.

In Visual Basic 6.0, you could create components that used Microsoft Message Queue (MSMQ) to pass information between applications. In Visual Basic .NET, messaging is built into the .NET Framework. For more information, see Creating Messaging Components.

In Visual Basic 6.0, you could create MTS components that worked with Microsoft Transaction Server (MTS) to participate in transactions. With Visual Basic .NET, transactions are handled by the .NET Framework by adding a Transactional Component to your project or by adding a Transaction attribute to an existing class.

Component Authoring | Inheritance | Introduction to Visual Basic .NET for Visual Basic Veterans | Component Model Namespaces in Visual Studio

UserControl Changes in Visual Basic .NET

In Visual Basic 6.0, UserControl projects (also known as ActiveX Control projects) were used to create ActiveX controls. After they were compiled, UserControls could be hosted in any container that supported ActiveX, including Visual Basic 6.0 forms and Internet Explorer.

In Visual Basic .NET, Windows Control Library projects are used to create controls that can be hosted in Windows Forms applications. When a Visual Basic 6.0 UserControl project is upgraded to Visual Basic .NET, it is upgraded to a Windows Control Library; the resulting control can no longer be hosted in Internet Explorer.

In Visual Basic 6.0, before adding a UserControl to a form at design time, you had to close the UserControl Designer; this step automatically compiled (built) the control. When subsequent changes were made to the UserControl, they would not be reflected in the instance of the UserControl on the form until the application was run; if open, the UserControl designer would automatically close.

In Visual Basic .NET, a UserControl can be added to a form without closing the UserControl Designer; however, the UserControl must be built before it can be added to a form. Simply closing the UserControl designer does not build the control. Any subsequent changes to the UserControl are not reflected on the form designer until the UserControl is rebuilt; a UserControl is automatically rebuilt each time you debug your test application.

In Visual Basic 6.0, the **ReadProperties** and **WriteProperties** events were used to retrieve or save a UserControl's values to a **PropertyBag** object.

In Visual Basic .NET, the **PropertyBag** object is no longer supported, and the **ReadProperties** and **WriteProperties** events no longer exist. Instead, serialization is used to save and retrieve properties in either a binary or SOAP format.

See Also

PropertyBag Changes in Visual Basic .NET | Walkthrough: Persisting an Object in Visual Basic .NET |
Control Authoring for Windows Forms | The contents of the template file were not upgraded |
WebClass state management is not supported | WebClass event is not supported

PropertyBag Changes in Visual Basic .NET

In Visual Basic 6.0, the **PropertyBag** object was used to persist an object's data between instances, allowing you to store values and retrieve them the next time the object was instantiated. Although you could set an object's properties to a default value at design time, any values entered at run time were lost when the object was destroyed. The **PropertyBag** object allowed a copy of the object to be persisted in a binary format and retrieved for later reuse. For example, a class used to calculate loans might use a **PropertyBag** object to persist an interest rate between instances, rather than entering it each time the class is used.

In Visual Basic .NET, the **PropertyBag** object no longer exists, but you can still persist an object's data using the **System.Runtime.Serialization** and **System.IO** namespaces. In addition to persisting an object in binary format, you can also persist an object in a SOAP format.

To persist an object in Visual Basic .NET, you first mark the class as **Serializable**. When instantiating the object, you use a **Stream** class and a **BinaryFormatter** or **SoapFormatter** class to retrieve the object's data from a file. Before destroying the object, you again use the **Stream** and formatter classes to write the object's values to the file.

For an example of how to persist an object, see Walkthrough: Persisting an Object.

Forms Changes in Visual Basic .NET

In Visual Basic 6.0 (and all earlier versions of Visual Basic), Windows applications were creating using forms that were an integral part of the Visual Basic runtime. In Visual Basic .NET, Windows applications are created using Windows Forms, which are provided by the .NET Framework.

Windows Forms and Windows Forms controls provide a richer, more extensible architecture for developing Windows applications; however, there are a number of differences between Windows Forms and controls and Visual Basic 6.0 Forms and controls. The following topics are designed to help you discover the differences.

In This Section

Forms Task Changes in Visual Basic .NET
Describes differences in common tasks for working with forms.
Control Changes in Visual Basic .NET

Forms Task Changes in Visual Basic .NET

There are many differences between Windows Forms and Visual Basic 6.0 Forms. The following table provides a list of tasks that can be performed with forms and their methodologies. You can use this list to transition your existing Visual Basic 6.0 Forms projects to the new .NET Framework model for Windows Forms.

Task	Visual Basic 6.0 Forms	Windows Forms
Set the Tab Indexing for all the controls on a form.	Select each control on the form and set its **TabIndex** property to the next number in the tab order for your form.	From the **View** menu choose **Tab Order**. The form displays a numeral next to each control that represents the control's TabIndex property setting. Click on each control in the desired tab order. For more information, see Setting the Tab Order on Windows Forms.
Determine the modifier key (ALT, SHIFT, CTRL) pressed during keyboard and mouse events.	Use the parameters provided by the mouse event handler.	Compare the Form class's ModifierKeys method against the modifier key value, found in the Keys enumeration. For more information, see Determining Which Modifier Key Was Pressed
Align or size controls based on the location and size of a single control.	Click on each control to align or size. The last control selected is used to determine the location and size of all controls selected.	Click on each control to align or size. The first control selected is used to determine the location and size of all controls selected. For more information, see Aligning Multiple Controls on Windows Forms.
Change the name of a form.	Change the name specified in the **Name** property of the form in the Properties window.	Click on the form's class file in the Solution Explorer and then change the **Filename** property in the Properties window.
Change the run-time display position of a form.	Use the Form Layout window to position the form, or set its **Startup** property in the Properties window.	With the form selected in the Windows Forms Designer, set the StartPosition property in the Properties window.
Display a form as a dialog box.	In code, use the **Show** method and specify that the form be displayed modally using the **vbModal** value.	In code, use the ShowDialog method of the form. For details, see Displaying Dialog Boxes for Windows Forms.
Group or layer controls on a form.	Layer the controls within the **Frame** control. To move the controls as a group, select them all.	Place the controls within a GroupBox control. Moving the group box moves the controls as well.
Iterate through the controls on a form.	Use a control array.	Use the Controls Collection. For details, see Collections in Visual Basic .NET.

App Object Changes in Visual Basic .NET

The **App** object in Visual Basic 6.0 was a global object used to set or retrieve information about the application. There is no direct equivalent for the **App** object in Visual Basic .NET; however, most of the properties can be mapped to equivalent properties in the .NET Framework.

> **Note** The **App** object's Version Information properties are replaced by Assembly attributes in Visual Basic .NET. Version Information properties were set in the Project Properties dialog box; Assembly attributes are set by editing the AssemblyInfo file in the Visual Basic .NET project. For more information, see Attributes.

App Object Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
Comments	**AssemblyDescription** attribute
CompanyName	**AssemblyCompany** attribute
EXEName	**System.Reflection.Assembly.GetExecutingAssembly.Location** **Note** The **Location** property returns the full path including the file name; the **EXEName** property returned only the file name.
FileDescription	**System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).FileDescription**
HelpFile	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
HInstance	**System.Runtime.InteropServices.Marshal.GetHINSTANCE(System.Reflection.Assembly.GetExecutingAssembly.GetModules()(0)).ToInt32**
LegalCopyright	**System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).LegalCopyright**
LegalTrademarks	**System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).LegalTrademarks**
LogEvent method	No equivalent. Logging in Visual Basic .NET is handled via Event Logs. For more information, see Creating and Removing Custom Event Logs.
LogMode	No equivalent. Logging in Visual Basic .NET is handled via Event Logs. For more information, see Creating and Removing Custom Event Logs.
LogPath	No equivalent. Logging in Visual Basic .NET is handled via Event Logs. For more information, see Creating and Removing Custom Event Logs.
Major	**System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).FileMajorPart** **Note** The format for version numbers is different in Visual Basic .NET. For more information, see Version Numbering Changes in Visual Basic .NET.
Minor	**System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).FileMinorPart** **Note** The format for version numbers is different in Visual Basic .NET. For more information, see Version Numbering Changes in Visual Basic .NET.
NonModalAllowed	No equivalent. This was a read-only property related to ActiveX .dll files. The .NET common language runtime automatically manages this behavior.
OleRequestPendingMsgText	No equivalent. This property relates to OLE automation, which is not supported by Visual Basic .NET.
OleRequestPendingMsgTitle	No equivalent. This property relates to OLE automation, which is not supported by Visual Basic .NET.
OleRequestPendingTimeout	No equivalent. This property relates to OLE automation, which is not supported by Visual Basic .NET.
OleServerBusyMsgText	No equivalent. This property relates to OLE automation, which is not supported by Visual Basic .NET.
OleServerBusyMsgTitle	No equivalent. This property relates to OLE automation, which is not supported by Visual Basic .NET.

OleServerBusyRaiseError	No equivalent. This property relates to OLE automation, which is not supported by Visual Basic .NET.
OleServerBusyTimeout	No equivalent. This property relates to OLE automation, which is not supported by Visual Basic .NET.
Path	**System.Reflection.Assembly.GetExecutingAssembly.Location** **Note** The **Location** property returns the full path including the file name; the **Path** property returned only the path.
PrevInstance	No equivalent. For more information, see PrevInstance Property Changes in Visual Basic .NET.
ProductName	**System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).ProductName**
RetainedProject	No equivalent. Visual Basic .NET does not have the ability to retain a project in memory.
Revision	**System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).FileBuildPart** – or – **System.Diagnostics.FileVersionInfo.GetVersionInfo(System.Reflection.Assembly.GetExecutingAssembly.Location).FilePrivatePart** **Note** The format for version numbers is different in Visual Basic .NET. For more information, see Version Numbering Changes in Visual Basic .NET.
StartLogging method	No equivalent. Logging in Visual Basic .NET is handled via Event Logs. For more information, see Creating and Removing Custom Event Logs.
StartMode	No equivalent. In Visual Basic 6.0, this property was used to start an application as an ActiveX component. ActiveX component creation is not supported in Visual Studio .NET.
TaskVisible	No equivalent. For more information, see TaskVisible Property Changes in Visual Basic .NET.
ThreadID	No equivalent. The threading model is different in Visual Basic .NET.
Title	No equivalent. In Visual Basic .NET, the **Text** property of the main form in the application determines the title that will be shown in the Task Manager.
UnattendedApp	No equivalent. For unattended applications in Visual Basic .NET, choose a Console Application project.

CheckBox Control Changes in Visual Basic .NET

The **CheckBox** control in Visual Basic 6.0 is replaced by the Windows Forms **CheckBox** control in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

CheckBox Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
Alignment **0 - Left Justify** **1 - Right Justify**	**CheckAlign** **System.Drawing.ContentAlignment.MiddleLeft** **System.Drawing.ContentAlignment.MiddleRight**
Appearance **0 – Flat** **1 - 3D**	**FlatStyle** **FlatStyle.Flat** **FlatStyle.Standard**
BackColor	**BackColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
Caption	**Text**
CausesValidation	**CausesValidation**
Container	**Parent**
DataChanged	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataField	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataFormat	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataMember	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataSource	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DisabledPicture	No equivalent. For more information, see Style Property Changes in Visual Basic .NET.
DownPicture	No equivalent. For more information, see Style Property Changes in Visual Basic .NET.
DragIcon	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Enabled	**Enabled**
Font	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontBold	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.

FontItalic	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontName	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontSize	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontStrikethru	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontUnderline	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
ForeColor	**ForeColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
Height	**Height, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
HelpContextID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
HWnd	**Handle**
Index	No equivalent. For more information, see Control Array Changes in Visual Basic .NET.
Left	**Left** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
MaskColor	No equivalent. For more information, see MaskColor Changes in Visual Basic .NET.
MouseIcon	No equivalent. For more information, see Cannot set a custom MousePointer.
MousePointer	**Cursor** For a list of constants, see MousePointer Changes in Visual Basic .NET.
Name	**Name**
OLEDropMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Parent	**FindForm** method
Picture	**Image**
RightToLeft **True** **False**	**RightToLeft** **RightToLeft.Yes** **RightToLeft.No**

Style **0 – Standard** **1 - Graphical**	**Appearance** **Note** There are differences in how the Graphical style is handled in Visual Basic .NET. For more information, see Style Property Changes in Visual Basic .NET. **Appearance.Normal** **Appearance.Button**
TabIndex	**TabIndex**
TabStop	**TabStop**
Tag	**Tag**
ToolTipText	**ToolTip** component For more information, see ToolTip Changes in Visual Basic .NET.
Top	**Top** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
UseMaskColor	No equivalent. For more information, see MaskColor Changes in Visual Basic .NET.
Value **0 – vbUnchecked** **1 – vbChecked** **2 - vbGrayed**	**CheckState** **CheckState.Unchecked** **CheckState.Checked** **CheckState.Indeterminate**
Visible	**Visible**
WhatsThisHelpID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
Width	**Width, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.

CheckBox Methods

Visual Basic 6.0	Visual Basic .NET Equivalent
Drag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Move	**SetBounds** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
OLEDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Refresh	**Refresh**
SetFocus	**Focus**
ShowWhatsThis	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
ZOrder **0 – vbBringToFront** **1 - vbSendToBack**	**BringToFront()** or **SendToBack()** functions **BringToFront()** **SendToBack()**

CheckBox Events

Visual Basic 6.0	Visual Basic .NET Equivalent
Click	**CheckStateChanged** **Note** In Visual Basic 6.0, the **Click** event was raised when the **CheckBox** state was changed programmatically. In Visual Studio .NET, the **Click** event is not raised; therefore, you should use the **CheckStateChanged** event.
DragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
GotFocus	**Enter**
KeyDown	**KeyDown**
KeyPress	**KeyPress**
KeyUp	**KeyUp**
LostFocus	**Leave**
MouseDown	**MouseDown**
MouseMove	**MouseMove**
MouseUp	**MouseUp**
OLECompleteDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEGiveFeedback	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLESetData	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEStartDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Validate	**Validating**

Introduction to the Windows Forms CheckBox Control

Clipboard Object Changes in Visual Basic .NET

The **Clipboard** object in Visual Basic 6.0 has no direct equivalent in Visual Basic .NET. Although there is no direct mapping, the functionality of the **Clipboard** object can be duplicated using the **System.Windows.Forms.Clipboard** namespace.

During upgrade, any code that references the **Clipboard** object is not upgraded and must be rewritten. The following example shows how to modify code that uses the **Clipboard** object:

```
' Visual Basic 6.0
Clipboard.Clear
Clipboard.SetText "hello", vbCFText

If Clipboard.GetFormat(vbCFText) Then
   Text1.Text = Clipboard.GetText(vbCFText)
End If
```

This can be rewritten as:

```
' Visual Basic .NET
Dim datobj As New System.Windows.Forms.DataObject

datobj.SetData System.Windows.Forms.DataFormats.Text, "hello"
System.Windows.Forms.Clipboard.SetDataObject datobj

If System.Windows.Forms.Clipboard.GetDataObject.GetDataPresent( _
   System.Windows.Forms.DataFormats.Text) Then
   Text1.Text = System.Windows.Forms.Clipboard.GetDataObject.GetData( _
   System.Windows.Forms.DataFormats.Text)
End If
```

Clipboard Constant Equivalents

Visual Basic 6.0	Visual Basic .NET Equivalent
vbCFBitmap	**System.Windows.Forms.DataFormats.Bitmap**
vbCFDIB	**System.Windows.Forms.DataFormats.DIB**
vbCFEMetafile	**System.Windows.Forms.DataFormats.EnhancedMetafile**
vbCFFiles	**System.Windows.Forms.DataFormats.FileDrop**
vbCFLink	No equivalent. For more information, see Dynamic Data Exchange Changes in Visual Basic .NET.
vbCFMetafile	**System.Windows.Forms.DataFormats.MetafilePict**
vbCFPalette	**System.Windows.Forms.DataFormats.Palette**
vbCFRTF	**System.Windows.Forms.DataFormats.Rtf**
vbCFText	**System.Windows.Forms.DataFormats.Text**

Note In addition to the formats listed above, Visual Basic .NET supports several clipboard formats that were not supported in Visual Basic 6.0.

Picture	**Image**
RightToLeft **True** **False**	**RightToLeft** **RightToLeft.Yes** **RightToLeft.No**
Style	**No equivalent.** For more information, see Style Property Changes in Visual Basic .NET.
TabIndex	**TabIndex**
TabStop	**TabStop**
Tag	**Tag**
ToolTipText	**ToolTip** component For more information, see ToolTip Changes in Visual Basic .NET.
Top	**Top** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
UseMaskColor	No equivalent. For more information, see MaskColor Changes in Visual Basic .NET.
Value	No equivalent. The **PerformClick** method is the same as setting the **Value** to **true**; for any other use of the **Value** property there is no equivalent.
Visible	**Visible**
WhatsThisHelpID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.

Width	**Width, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.

CommandButton Methods

Visual Basic 6.0	Visual Basic .NET Equivalent
Drag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Move	**SetBounds** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
OLEDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Refresh	**Refresh**
SetFocus	**Focus**
ShowWhatsThis	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
ZOrder **0 – vbBringToFront** **1 - vbSendToBack**	**BringToFront()** or **SendToBack()** functions **BringToFront()** **SendToBack()**

CommandButton Events

Visual Basic 6.0	Visual Basic .NET Equivalent
Click	**Click**
DragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
GotFocus	**Enter**
KeyDown	**KeyDown**
KeyPress	**KeyPress**
KeyUp	**KeyUp**
LostFocus	**Leave**
MouseDown	**MouseDown**
MouseMove	**MouseMove**
MouseUp	**MouseUp**
OLECompleteDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEGiveFeedback	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLESetData	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEStartDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.

Introduction to the Windows Forms Button Control

Controls Collection Changes in Visual Basic .NET

In Visual Basic 6.0, the **Controls** collection was a collection whose elements represented the controls on a form or container control. In Visual Basic .NET, the **System.Windows.Forms.Control.ControlCollection** class replaces the **Controls** collection. Forms have a default **ControlCollection** class that can be accessed using the syntax `Me.Controls`.

There are some differences in behavior:

- In Visual Basic 6.0, the **Add** method of the **Controls** collection was late-bound; controls were created in the **Add** method by specifying the control class as an argument. In Visual Basic .NET. the **Add** method of a **Controls** collection class requires that the controls have already been created before being added to the collection.

  > **Note** Because of this and other differences between Visual Basic 6.0 and Visual Basic .NET Controls collections, calls to the **Add** method are not upgraded. You must add code to recreate your application's behavior using the new **Controls.Add** method.

- In Visual Basic 6.0, the **Timer** and **Menu** controls were members of the **Controls** collection. In Visual Basic .NET they are replaced by the **Timer** and **MainMenu** components; components are not members of the **ControlCollection** class.
- The **Controls** collection included controls that were children of a container control (for example, controls sited on a **Frame** control); the **ControlCollection** class does not.
- Members of the **Controls** collection could be referenced using either the index or the name of the control; the **ControlCollection** class only supports the index.
- The **Remove** method of the **Controls** collection could only be used for controls that had been added using the **Add** method; the **ControlCollection** class does not have this restriction.

The following example illustrates some of the differences:

```
' Visual Basic 6.0
Private Sub Command1_Click()
    Dim c As Control
    Set c = Controls.Add("VB.TextBox", "Text1")
    c.Visible = True
    c.Text = "Hello"
    If Controls.Count > 1 Then
        MsgBox (Controls("Text1").Text)
    End If
    ' The following line causes a compilation error.
    Controls.Remove (Command1)
End Sub

' Visual Basic .NET
Private Sub button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
button1.Click
    Dim textBox1 As New System.Windows.Forms.TextBox
    textBox1.Text = "Hello"
    Me.Controls.Add(textBox1)
    If Me.Controls.Count > 1 Then
        MsgBox(Me.Controls(Me.Controls.IndexOf(textBox1)).Text)
    End If
    Me.Controls.Remove(button1)
End Sub
```

Data Control Changes in Visual Basic .NET

The Visual Basic 6.0 Data Control was used as a mechanism for binding controls to a database using DAO. Visual Basic .NET has no equivalent for the Data Control; the data-binding architecture has changed and DAO is no longer supported. For more information, see Data Changes in Visual Basic .NET.

Things to Consider Before Upgrading | Data Changes in Visual Basic .NET

DataGrid Control Changes in Visual Basic .NET

The **DataGrid** control in Visual Basic 6.0 is replaced by the Windows Forms **DataGrid** control in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior. The following table lists Visual Basic 6.0 properties and their Visual Basic .NET equivalents.

The Visual Basic .NET **DataGrid** control does not need data-specific methods or events because all actions are performed through the data source. Because of this separation of presentation and data functionality, the data source can be changed with or without user interface input. Also, multiple controls bound to the same data source will always stay in sync.

Properties for viewing and navigation in the **DataGrid** (such as **TabAction**, **EnterAction**, **AllowArrows**, **WrapCellPointer**, and **Scrollable**) are no longer needed. For example, the grid functions as though the **Scrollable** property is set to **true**: If more data exists than can be displayed, a scroll bar appears automatically. Excel-style navigation through the grid is the default, allowing the user to move forward with the TAB key and backward with the SHIFT+TAB key combination. For details, see Keyboard Shortcuts for the Windows Forms DataGrid Control.

DataGrid Properties

Visual Basic 6.0	**Visual Basic .NET Equivalent**
AddNewMode	No equivalent.
Align	**Dock** and **Anchor**
AllowAddNew	On **DataView** object; accessed through **AllowNew** property of **DataView** class.
AllowArrows	No longer an adjustable property: arrow navigation always allowed.
AllowDelete	On **DataView** object; accessed through **AllowDelete** property of **DataView** class.
AllowRowSizing	No longer an adjustable property: row sizing always allowed.
AllowUpdate	On **DataView** object; accessed through **AllowEdit** property of **DataView** class.
Appearance	**BorderStyle**
ApproxCount	On **BindingManagerBase** object, returned by **BindingContext** object; accessed through **Count** property of the **BindingManagerBase** class.
BackColor	**BackColor** affects only odd-numbered rows; **AlternatingBackColor** affects only even-numbered rows. **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
Bookmark	You can now directly access any item.
Caption	**CaptionText**
CausesValidation	**CausesValidation**
Col	On the **DataGridCell** structure; accessed by **DataGrid.CurrentCell.ColumnNumber**
ColumnHeaders	**ColumnHeadersVisible** **RowHeadersVisible**
Columns	On the **DataGridTableStyle** object; accessed by **DataGrid.TableStyle.GridColumnStyles**.
Container	**Parent**; inherited from **Control**.
CurrentCellModified	**RowState** property on **DataRow** object.

CurrentCellVisible	If **CurrentCell** properties are set to a cell that is not visible, the grid will scroll to show that cell (similar to **CurrentCellVisible** = **true**).
DataBindings	**DataBindings**
DataChanged	On **DataTable** object; accessed by **GetChanges** method of **DataTable** class.
DataFormats	**Format** property on **DataGridTextBoxColumn** object.
DataMember	**DataMember**
DataSource	**DataSource**
DefColWidth	**PreferredColumnWidth**
DragIcon	See GiveFeedbackEventArgs Class.
DragMode	See Control.DoDragDrop Method.
EditActive	No equivalent.
Enabled	**Enabled**
ErrorText	On **DataRow** object; accessed by **RowError** property of **DataRow** class.
FirstRow	Set **Position** property to 0 on **BindingManagerBase** object
Font	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET
ForeColor	**ForeColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
HeadFont	**HeaderFont** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET
HeadLines	No equivalent.
Height	**Height**, inherited from **Control** class **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
HelpContextID	On **HelpProvider** extender control; accessed by **SetHelpKeyword** method of **HelpProvider** control.
hWnd	**Handle**
hWndEditor	No equivalent.
Index	No equivalent.
Left	**Left**
LeftCol	No equivalent.
MarqueeStyle	Cell is highlighted when selected
Name	Not available at run time

Object	No equivalent.
Parent	**Parent**, inherited from **Control** class
RecordSelectors	**RowHeadersVisible**
RightToLeft	**RightToLeft**
Row	On **DataGridCell** structure; accessed by **DataGrid.CurrentCell.RowNumber**.
RowDividerStyle	**GridLineStyle**
RowHeight	No equivalent.
ScrollBars	No longer an adjustable property; the default behavior is **ScrollBars** = **true**.
SelBookmarks	No equivalent.
SelEndCol	No equivalent.
SelLength	No equivalent.
SelStart	No equivalent.
SelStartCol	No equivalent.
SelText	No equivalent.
Split	No equivalent.
Splits	No equivalent.
TabAcrossSplits	No equivalent.
TabAction	No longer an adjustable property. The default behavior is for the focus to move to the next column when the TAB key is pressed (**dbgColumnNavigation**). You can move the focus to the next control on the form (**dbgControlNavigation**) by pressing CTRL+TAB.
TabIndex	**TabIndex**
TabStop	**TabStop**
Tag	No equivalent.
Text	**Item**, when set to the current cell. For example: `Dim SelectedCellText As String = DataGrid1.Item(DataGrid1.CurrentCell)`
ToolTipText	On **ToolTip** extender control; accessed by **SetToolTip** method of **ToolTip** control
Top	**Top**
Visible	**Visible**
VisibleCols	**VisibleColumnCount**
VisibleRows	**VisibleRowCount**
WhatsThisHelpID	On **HelpProvider** extender control; accessed by **SetHelpString** method of **HelpProvider** control
Width	**Width**, inherited from **Control** class **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
WrapCellPointer	No longer an adjustable property; default behavior is **WrapCellPointer** = **true**.

DirListBox Control Changes in Visual Basic .NET

The Visual Basic 6.0 **DirListBox** control was typically used to display directories and paths in a File Open or Save dialog box. Visual Basic .NET has no equivalent for the **DirListBox** control; however, the Windows Forms **OpenFileDialog** and **SaveFileDialog** controls provide the ability to create standard Windows dialog boxes for working with files.

During upgrade, any existing **DirListBox** controls are upgraded to the **VB6.DirListBox** control that is provided as a part of the compatibility library (Microsoft.VisualBasic.Compatibility).

Font Object Changes in Visual Basic .NET

In Visual Basic 6.0, **Font** properties could be set via a **stdFont** object rather than setting the properties directly. The Visual Basic 6.0 **stdFont** object is replaced in Visual Basic .NET by the **System.Drawing.Font** class; there is no direct mapping of the properties and methods. For more information, see Font Changes in Visual Basic .NET.

Form Object Changes in Visual Basic .NET

The **Form** object in Visual Basic 6.0 is replaced by the **System.Windows.Forms.Form** class in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

Form Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
ActiveControl	**ActiveControl**
Appearance	No equivalent. For more information, see Appearance and BorderStyle Property Changes in Visual Basic .NET.
AutoRedraw	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
BackColor	**BackColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
BorderStyle **0 – None** **1 – Fixed Single** **2 – Sizable** **3 – Fixed Dialog** **4 – Fixed Tool Window** **5 – Sizable ToolWindow**	**FormBorderStyle** **0 – FormBorderStyle.None** **1 – FormBorderStyle.FixedSingle** **4 – FormBorderStyle.Sizable** **3 – FormBorderStyle.FixedDialog** **5 – FormBorderStyle.FixedToolWindow** **6 – FormBorderStyle.SizableToolWindow**
Caption	**Text**
ClipControls	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
ControlBox	**ControlBox**
Controls	**Controls** **Note** There are differences in the **Controls** collection in Visual Basic .NET. For more information, see Controls Collection Changes in Visual Basic .NET.
Count	**Controls.Count** **Note** There are differences in the **Controls** collection in Visual Basic .NET. For more information, see Controls Collection Changes in Visual Basic .NET.
CurrentX	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
CurrentY	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
DrawMode	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
DrawStyle	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
DrawWidth	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Enabled	**Enabled**
FillColor	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
FillStyle	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.

Font	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontBold	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontItalic	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontName	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontSize	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontStrikethru	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontUnderline	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
ForeColor	**ForeColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
HasDC	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
HDC	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Height	**Height, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
HelpContextID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
HWnd	**Handle**
Icon	**Icon**
Image	No equivalent. The **Image** property in Visual basic 6.0 returned a handle to a bitmap; images in Visual Basic .NET do not have handles.
KeyPreview	**KeyPreview**
Left	**Left** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
LinkMode	No equivalent. For more information, see Dynamic Data Exchange Changes in Visual Basic .NET.
LinkTopic	No equivalent. For more information, see Dynamic Data Exchange Changes in Visual Basic .NET.
MaxButton	**MaximizeBox**

MDIChild	**MDIParent** **Note** MDI behavior is different in Visual Basic .NET. For more information, see MDI Changes in Visual Basic .NET.
MinButton	**MinimizeBox**
MouseIcon	No equivalent. For more information, see Cannot set a custom MousePointer.
MousePointer	**Cursor** For a list of constants, see MousePointer Changes in Visual Basic .NET.
Moveable	No equivalent. For more information, see Moveable Property Changes in Visual Basic .NET.
Name	**Name**
NegotiateMenus	No equivalent. For more information, see Menu Changes in Visual Basic .NET.
OLEDropMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Palette	No equivalent. For more information, see Palette Changes in Visual Basic .NET.
PaletteMode	No equivalent. For more information, see Palette Changes in Visual Basic .NET.
Picture	**BackgroundImage** **Note** In Visual Basic 6.0, the **Picture** was displayed in the top left corner of the form; in Visual Basic .NET, the **BackgroundImage** is tiled.
RightToLeft **True** **False**	**RightToLeft** **RightToLeft.Yes** **RightToLeft.No**
ScaleHeight	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
ScaleLeft	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
ScaleMode	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
ScaleTop	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
ScaleWidth	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
ShowInTaskbar	**ShowInTaskBar**
StartUpPosition **0 – Manual** **1 – CenterOwner** **2 – CenterScreen** **3 – Windows Default**	**StartPositionMapping** **0 – FormStartPosition.Manual** **4 – FormStartPosition.CenterParent** **1 – FormStartPosition.CenterScreen** **2 – FormStartPosition.WindowsDefaultLocation**
Tag	**Tag**
Top	**Top** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
Visible	**Visible**
WhatsThisButton	**HelpButton** **Note** There are differences in Help behavior in Visual Basic .NET. For more information, see Help Support Changes in Visual Basic .NET.
WhatsThisHelp	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
Width	**Width, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.

WindowState	**WindowState**

Form Methods

Visual Basic 6.0	**Visual Basic .NET Equivalent**
Circle	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Cls	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Hide	**Hide**
Line	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Move	**SetBounds** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
OLEDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
PaintPicture	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Point	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
PopupMenu	No equivalent. For more information, see Menu Changes in Visual Basic .NET.
PrintForm	No equivalent. For more information, see Printing Changes in Visual Basic .NET.
Pset	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Refresh	**Refresh**
Scale	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
ScaleX	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
ScaleY	No equivalent. For more information, see Coordinate System Changes in Visual Basic .NET.
SetFocus	**Activate**
Show	**Show** or **ShowDialog**
TextHeight	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
TextWidth	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
ValidateControls	**Validate** **Note** The **Validate** method returns **true** or **false**; **ValidateControls** raised an error if validation failed .
WhatsThisMode	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
ZOrder **0 – vbBringToFront** **1 - vbSendToBack**	**BringToFront()** or **SendToBack()** functions **Note** In Visual Basic 6.0, the **ZOrder** method positioned the form relative to other forms in the applicat ion; in Visual Basic .NET, forms are positioned relative to all windows on the screen. **BringToFront()** **SendToBack()**

Form Events

Visual Basic 6.0	**Visual Basic .NET Equivalent**
Activate	**Activated** **Note** In Visual Basic 6.0, the **Activate** event was raised only when switching between forms in the applicat ion; in Visual Basic .NET, the **Activated** event also is raised when switching from other applications.
Click	**Click** **Note** The **Click** event is not supported for MDI Forms.

DblClick	**DoubleClick**
Deactivate	**Deactivate** **Note** In Visual Basic 6.0, the **Deactivate** event was raised only when switching between forms in the application; in Visual Basic .NET, it also is raised when switching to other applications.
DragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
GotFocus	**Enter**
Initialize	**New** method **Note** The behavior of the **New** method is different than the **Initialize** event. For more information, see Form Event Changes in Visual Basic .NET.
KeyDown	**KeyDown**
KeyPress	**KeyPress**
KeyUp	**KeyUp**
LinkClose	No equivalent. For more information, see Dynamic Data Exchange Changes in Visual Basic .NET.
LinkError	No equivalent. For more information, see Dynamic Data Exchange Changes in Visual Basic .NET.
LinkExecute	No equivalent. For more information, see Dynamic Data Exchange Changes in Visual Basic .NET.
LinkOpen	No equivalent. For more information, see Dynamic Data Exchange Changes in Visual Basic .NET.
Load	**Load**
LostFocus	**LostFocus**
MouseDown	**MouseDown** **Note** The **MouseDown** event is not supported for MDI Forms.
MouseMove	**MouseMove** **Note** The **MouseMove** event is not supported for MDI Forms.
MouseUp	**MouseUp** **Note** The **MouseUp** event is not supported for MDI Forms.
OLECompleteDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEGiveFeedback	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLESetData	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEStartDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Paint	**Paint**

QueryUnload	**Closing** **Note** In Visual Basic 6.0, **QueryUnload** took two arguments, Cancel and UnloadMode. In Visual Basic .NET, Cancel can be replaced by using **System.ComponentModel.CancelEventArgs.Cancel**. There is no replacement for UnloadMode.
Resize	**Resize**
Terminate	**Dispose** method **Note** The behavior of the **Dispose** method is different than the **Terminate** event. For more information, see Form Event Changes in Visual Basic .NET.
Unload	**Closed** **Note** The behavior of the **Closed** event is different than the **Unload** event. For more information, see Form Event Changes in Visual Basic .NET.

Forms Collection Changes in Visual Basic .NET

In Visual Basic 6.0, the **Forms** collection was a collection whose elements represented each loaded form in an application. There is no equivalent for the **Forms** collection in Visual Basic .NET.

If you need the functionality of the **Forms** collection, you can create your own collection class and add or remove references to forms as the forms are loaded or unloaded. For more information, see Walkthrough: Creating Your Own Collection Class.

Form Object Changes in Visual Basic .NET | Walkthrough: Creating Your Own Collection Class

Frame Control Changes in Visual Basic .NET

In Visual Basic 6.0, the **Frame** control was used as a container for grouping controls. In Visual Basic .NET, the **Frame** control is replaced by either the **GroupBox** control or the **Panel** control.

The **GroupBox** control is the equivalent of a **Frame** control with a **BorderStyle** property of **1 – Fixed Single**. It has a visible border and optionally a caption.

The **Panel** control is the equivalent of a **Frame** control with a **BorderStyle** property of **0 – None.** It has no border or caption.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

Frame Properties

Visual Basic 6.0	**Visual Basic .NET Equivalent**
Appearance **0 – Flat** **1 - 3D**	**FlatStyle** (**GroupBox** control only) **Note** The **Panel** control does not have a direct equivalent. For more information, see Appearance and BorderStyle Property Changes in Visual Basic .NET. **FlatStyle.Flat** **FlatStyle.Standard**
BackColor	**BackColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
BorderStyle **0 – None** **1 – Fixed Single**	**BorderStyle** (**GroupBox** control only) **Note** The **Panel** control does not have a direct equivalent. For more information, see Appearance and BorderStyle Property Changes in Visual Basic .NET. **0 – BorderStyle.None** **1 – BorderStyle.FixedSingle**
Caption	**Text** (**GroupBox** control only) **Note** The **Panel** control does not have a **Text** property.
ClipControls	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Container	**Parent**
DragIcon	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Enabled	**Enabled**
Font	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontBold	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.

FontItalic	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontName	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontSize	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontStrikethru	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontUnderline	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
ForeColor	**ForeColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
Height	**Height, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
HelpContextID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
HWnd	**Handle**
Index	No equivalent. For more information, see Control Array Changes in Visual Basic .NET.
Left	**Left** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
MouseIcon	No equivalent. For more information, see Cannot set a custom MousePointer.
MousePointer	**Cursor** For a list of constants, see MousePointer Changes in Visual Basic .NET.
Name	**Name**
OLEDropMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Parent	**FindForm** method
RightToLeft **True** **False**	**RightToLeft** **RightToLeft.Yes** **RightToLeft.No**
TabIndex	**TabIndex**
Tag	**Tag**
ToolTipText	**ToolTip** component For more information, see ToolTip Changes in Visual Basic .NET.

HScrollBar Control Changes in Visual Basic .NET

The **HScrollBar** control in Visual Basic 6.0 is replaced by the Windows Forms **HScrollBar** control in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

HScrollBar Properties

Visual Basic 6.0	**Visual Basic .NET Equivalent**
CausesValidation	**CausesValidation**
Container	**Parent**
DragIcon	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Enabled	**Enabled**
Height	**Height, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
HelpContextID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
HWnd	**Handle**
Index	No equivalent. For more information, see Control Array Changes in Visual Basic .NET.
LargeChange	**LargeChange** **Note** The default value in Visual Basic 6.0 was 1, in Visual Basic .NET the default value is 10.
Left	**Left** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
Max	**Maximum** **Note** The default value in Visual Basic 6.0 was 32767, in Visual Basic .NET the default value is 100.
Min	**Minimum** **Note** In Visual Basic 6.0 **Min** could be set to a value greater than **Max**; in Visual Basic .NET this is not allowed.
MouseIcon	No equivalent. For more information, see Cannot set a custom MousePointer.
MousePointer	**Cursor** For a list of constants, see MousePointer Changes in Visual Basic .NET.
Name	**Name**
Parent	**FindForm** method
RightToLeft **True** **False**	**RightToLeft** **RightToLeft.Yes** **RightToLeft.No**

Image Control Changes in Visual Basic .NET

The **Image** control in Visual Basic 6.0 has no direct equivalent in Visual Basic .NET. The **Image** control was a lightweight control; Visual Basic .NET does not support lightweight controls.

During upgrade, **Image** controls are upgraded to the Visual Basic .NET Windows Forms **PictureBox** control. The properties, methods, and events for the **Image** control were a subset of those for the **PictureBox** control (with the exception of the **Stretch** property). For more information, see PictureBox Control Changes in Visual Basic .NET.

The following table shows the mapping between the **Stretch** property and the equivalent for the Visual Basic .NET **PictureBox** control.

Stretch property equivalents

Visual Basic 6.0	Visual Basic .NET Equivalent
Stretch = **False**	**SizeMode** = **System.Windows.Forms.PictureBoxSizeMode.Normal**
Stretch = **True**	**SizeMode** = **System.Windows.Forms.PictureBoxSizeMode.StretchImage**

Line Control Changes in Visual Basic .NET

The **Line** control in Visual Basic 6.0 has no equivalent in Visual Basic .NET. During upgrade, vertical or horizontal **Line** controls are replaced with the Windows Forms **Label** control, with the **Text** property set to an empty string, the **BorderStyle** property set to **none**, and the **BackColor**, **Width,** and **Height** properties set to match the original control.

Line controls that were not vertical or horizontal are not upgraded. You can replace the **Line** control using the graphics functions built into the .NET Framework. For more information, see Graphics Changes in Visual Basic .NET.

Graphics Changes in Visual Basic .NET

ListBox Control Changes in Visual Basic .NET

The **ListBox** control in Visual Basic 6.0 is replaced by either the Windows Forms **ListBox** control or the **CheckedListBox** control in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior.

During upgrade, if the **Style** property of a Visual Basic 6.0 **Listbox** is set to **1 – Checkbox**, it is upgraded to the **CheckedListBox** control; otherwise, it is upgraded to the **ListBox** control.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

ListBox Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
Appearance	No equivalent. For more information, see Appearance and BorderStyle Property Changes in Visual Basic .NET.
BackColor	**BackColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
CausesValidation	**CausesValidation**
Columns	**MultiColumn** and **ColumnWidth** **Note** The **Columns** property took an integer specifying the number of columns. The **MultiColumn** property takes a Boolean value, and the **ColumnWidth** property takes an integer specifying the width in pixels. If the width of the **ListBox** control is changed at run time, you may also need to set the **ColumnWidth** property for each column.
Container	**Parent**
DataChanged	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataField	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataFormat	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataMember	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataSource	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DragIcon	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.

DragMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Enabled	**Enabled**
Font	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.

FontStrikethru	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
FontUnderline	**Font** **Note** Fonts are handled differently in Visual Basic .NET. For more information, see Font Changes in Visual Basic .NET.
ForeColor	**ForeColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
Height	**Height, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
HelpContextID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
HWnd	**Handle**
Index	No equivalent. For more information, see Control Array Changes in Visual Basic .NET.
IntegralHeight	**IntegralHeight**
ItemData	No equivalent. For more information, see ItemData property cannot be upgraded.

Left	**Left** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
List	**Items**
ListCount	**Items.Count**
ListIndex	**SelectedIndex**
MouseIcon	No equivalent. For more information, see Cannot set a custom MousePointer.
MousePointer	**Cursor** For a list of constants, see MousePointer Changes in Visual Basic .NET.
MultiSelect **0 – None** **1 – Simple** **2 – Extended**	**SelectionMode** **SelectionMode.One** **SelectionMode.MultiSimple** **SelectionMode.MultiExtended**
Name	**Name**
NewIndex	No equivalent. For more information, see NewIndex property cannot be upgraded.
OLEDragMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDropMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Parent	**FindForm** method
RightToLeft **True** **False**	**RightToLeft** **RightToLeft.Yes** **RightToLeft.No**
SelCount	**SelectedItems.Count**
Selected	**GetSelected, SetSelected** (**ListBox** control) **GetItemChecked, SetItemChecked** (**CheckedListBox** control)
Sorted	**Sorted**

Style **0 - Standard** **1 - Checkbox**	No equivalent property. **0 – Standard** maps to the **ListBox** control, **1 – Checkbox** maps to the **CheckedListBox** control.
TabIndex	**TabIndex**
TabStop	**TabStop**
Tag	**Tag**
Text	**Text**
ToolTipText	**ToolTip** component For more information, see ToolTip Changes in Visual Basic .NET.
Top	**Top** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
TopIndex	**TopIndex**
Visible	**Visible**
WhatsThisHelpID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
Width	**Width, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.

ListBox Methods

Name	Visual Basic .NET Equivalent
AddItem	**Items.Insert** or **Items.Add**
Clear	**Items.Clear**
Drag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Move	**SetBounds** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
OLEDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Refresh	**Refresh**
RemoveItem	**Items.Remove**
SetFocus	**Focus**
ShowWhatsThis	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.

ZOrder **0 – vbBringToFront** **1 - vbSendToBack**	**BringToFront()** or **SendToBack()** functions **BringToFront()** **SendToBack()**

ListBox Events

Visual Basic 6.0	**Visual Basic .NET Equivalent**
Click	**SelectedIndexChanged** **Note** In Visual Basic 6.0, the **Click** event was raised when the **CheckBox** state was changed programmatically. In Visual Studio .NET, the **Click** event is not raised; therefore, you should use the **CheckStateChanged** event.
DblClick	No equivalent. Use the **SelectedIndexChanged** or **TextChanged** events.
DragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
GotFocus	**Enter**
ItemCheck	**ItemCheck** (**CheckedListBox** only) **Note** In Visual Basic 6.0, when an event was raised, the check state was already changed. In Visual Basic .NET, the check state has not yet changed. You can get the pending value from the **ItemCheckEventArgs** argument passed to the event.
KeyDown	**KeyDown**
KeyPress	**KeyPress**
KeyUp	**KeyUp**
LostFocus	**Leave**
MouseDown	**MouseDown**
MouseMove	**MouseMove**
MouseUp	**MouseUp**
OLECompleteDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragDrop	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEDragOver	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEGiveFeedback	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLESetData	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
OLEStartDrag	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Scroll	No equivalent. For more information, see TopIndex Property and Scroll Event Changes in Visual Basic .NET.

Introduction to the Windows Forms ListBox Control

MDIForm Object Changes in Visual Basic .NET

In Visual Basic 6.0, an **MDIForm** was a special type of form that acted as a container for an MDI application. In VisualBasic .NET, an **MdiForm** is any form with the **IsMdiContainer** property set to **true**.

In Visual Basic 6.0, setting the **MDIChild** property on a child form identified it as a child of the MDI form; an MDI application could have only one MDI form. In Visual Basic .NET, the **MdiParent** property replaces the **MDIChild** property and identifies the MDI form that will contain the child form; MDI applications can have multiple MDI containers.

The following table lists Visual Basic 6.0 properties and methods and their Visual Basic .NET equivalents. Only properties and methods that are unique to the **MDIForm** object are listed — for other properties, methods, and events see Form Object Changes in Visual Basic .NET.

MDIForm Properties and Methods

Visual Basic 6.0	**Visual Basic .NET Equivalent**
ActiveForm property	**ActiveMdiCHild**
Arrange method **0 - vbCascade** **1 – vbTileHorizontal** **2 – vbTileVertical** **3 – vbArrangeIcons**	**LayoutMdi** **0 - MdiLayout.Cascade** **1 - MdiLayout.TileHorizontal** **2 - MdiLayout.TileVertical** **3 - MdiLayout.ArrangeIcons**
AutoShowChildren property	No equivalent. For more information, see MDI form Show behavior has changed.
BackColor property	No equivalent. The **BackColor** for an MDI form will always be the default.
Picture property	No equivalent. MDI forms in Visual Basic .NET cannot display pictures.

Menu Object Changes in Visual Basic .NET

In Visual Basic 6.0, a **Menu** object was created using the Menu Editor. **Menu** objects were tied to the form for which they were created, but they could be modified at run time or displayed as context menus.

In Visual Basic .NET, the **Menu** object is replaced by the **MainMenu** and **ContextMenu** controls. Menus may be created using the Windows Forms Designer or they may be created in code.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where there are no direct equivalents, links are provided to additional information. Unless otherwise noted, all objects are in the **System.Windows.Forms** namespace.

Menu Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
Caption	**Text**
Checked	**Checked**
Enabled	**Enabled**
HelpContextID	No equivalent. For details, see Help Support Changes in Visual Basic .NET.
Index	No direct equivalent. Use the **MenuItemCollection** class.
Name	**Name**
NegotiatePosition	No equivalent. This property was only used for OLE linking and embedding.
Parent	**GetMainMenu().GetForm()**
Shortcut	**Shortcut**
Tag	No equivalent. Tags for menu items are not supported.
Visible	**Visible**
WindowList	**MdiList**

Menu Events

Visual Basic 6.0	Visual Basic .NET Equivalent
Click	**Click** or **Popup**. **Note** The **Popup** event is raised prior to the **Click** event when a menu item has children.

See Also

OLE Container Control Changes in Visual Basic .NET

In Visual Basic 6.0, the **OLE Container** control was used to add insertable OLE objects to your forms. There is no **OLE Container** control in Visual Basic .NET. If you need the functionality of the **OLE Container** control, in some cases you can substitute the Visual Basic 6.0 **WebBrowser** ActiveX control and use it as an **OLE Container**.

Things to Consider Before Upgrading | Adding ActiveX Controls to Windows Forms

OptionButton Control Changes in Visual Basic .NET

The **OptionButton** control in Visual Basic 6.0 is replaced by the Windows Forms **RadioButton** control in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

OptionButton Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
Alignment **0 - Left Justify** **1 - Right Justify**	**TextAlign** **System.Drawing.ContentAlignment.MiddleLeft** **System.Drawing.ContentAlignment.MiddleRight**
Appearance **0 – Flat** **1 – 3D**	**FlatStyle** **FlatStyle.Flat** **FlatStyle.Standard**
BackColor	**BackColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
Caption	**Text**
CausesValidation	**CausesValidation**

Introduction to the Windows Forms RadioButton Control

PictureBox Control Changes in Visual Basic .NET

The **PictureBox** control in Visual Basic 6.0 is replaced by the Windows Forms **PictureBox** control in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior.

The Visual Basic 6.0 **PictureBox** control was a container control; the Visual Basic .NET **PictureBox** control is not. During upgrade, **PictureBox** controls that contain controls are upgraded to **Panel** controls.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

PictureBox Properties

Visual Basic 6.0	**Visual Basic .NET Equivalent**
Align **0 – None** **1 – Top** **2 – Bottom** **3 – Left** **4 – Right**	**Dock** **DockStyle.None** **DockStyle.Top** **DockStyle.Bottom** **DockStyle.Left** **DockStyle.Right**
Appearance	No equivalent. For more information, see Appearance and BorderStyle Property Changes in Visual Basic .NET.
AutoRedraw	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
AutoSize **False** **True**	**PictureBoxSizeMode** **Note** For **PictureBox** controls that are upgraded to **Panel** controls, there is no equivalent for **AutoSize**. **PictureBoxSizeMode.Normal** **PictureBoxSizeMode.AutoSize**
BackColor	**BackColor** **Note** Colors are handled differently in Visual Basic .NET. For more information, see Color Behavior Changes in Visual Basic .NET. For a list of constants, see Color Changes in Visual Basic .NET.
BorderStyle **0 – None** **1 – Fixed Single**	**Borderstyle** **Note** In Visual Basic 6.0, the default was **1 – Fixed Single**, in Visual Basic .NET the default is **None**. **BorderStyle.None** **BorderStyle.FixedSingle**
CausesValidation	**CausesValidation**
ClipControls	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
Container	**Parent**
CurrentX	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.
CurrentY	No equivalent. For more information, see Graphics Changes in Visual Basic .NET.

Introduction to the Windows Forms PictureBox Control

Printer Object Changes in Visual Basic .NET

The **Printer** object in Visual Basic 6.0 is replaced by the **PrintDocument** component in Visual Basic .NET. The behavior is different, but in most cases the functionality can be duplicated.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where there are no direct equivalents, links are provided to additional information. Unless otherwise noted, all objects are in the **System.Drawing** namespace.

Printer Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
ColorMode	No longer necessary. This property controlled whether output would be printed in monochrome on a color printer; it is now up to the printer to expose this as an advanced option. The **SupportsColor** property of the **PrinterSettings** class can be used to determine the color capabilities of a printer.
Copies	**Copies** property of the **PrinterSettings** class.
CurrentX	No equivalent. Replaced by location and dimension arguments of various methods of the **Graphics** class.
CurrentY	No equivalent. Replaced by location and dimension arguments of various methods of the **Graphics** class.
DeviceName	**PrinterName** property of the **PrinterSettings** class.
DrawMode	No equivalent. For details, see Graphics Changes in Visual Basic .NET.
DrawStyle	No equivalent. For details, see Graphics Changes in Visual Basic .NET.
DrawWidth	No equivalent. For details, see Graphics Changes in Visual Basic .NET.
DriverName	No equivalent. No longer needed; printer drivers are managed by Windows.
Duplex	**Duplex** property of the **PrinterSettings** class.
FillColor	No equivalent. For details, see Graphics Changes in Visual Basic .NET.
FillStyle	No equivalent. For details, see Graphics Changes in Visual Basic .NET.
Font	No equivalent. For details, see Font Changes in Visual Basic .NET.
FontBold	No equivalent. For details, see Font Changes in Visual Basic .NET.
FontCount	No equivalent. For details, see Font Changes in Visual Basic .NET.
FontItalic	No equivalent. For details, see Font Changes in Visual Basic .NET.
FontName	No equivalent. For details, see Font Changes in Visual Basic .NET.
Fonts	No equivalent. For details, see Font Changes in Visual Basic .NET.
FontSize	No equivalent. For details, see Font Changes in Visual Basic .NET.
FontStrikeThru	No equivalent. For details, see Font Changes in Visual Basic .NET.
FontTransparent	No equivalent. For details, see Font Changes in Visual Basic .NET.

FontUnderline	No equivalent. For details, see Font Changes in Visual Basic .NET.
ForeColor	No equivalent. For details, see Color Behavior Changes in Visual Basic .NET.
hDC	No longer necessary. An instance of a **PrintDocument** component is the equivalent of a device context. **Note** Graphics objects have **GetHDC** and **ReleaseHDC** methods that can be used in advanced scenarios.
Height	**PaperSize** property of the **PageSettings** class.
Orientation	**Landscape** property of the **PageSettings** class.
Page	No equivalent. The current page number is not tracked; however, you can easily do this by setting a variable in the **Begin Print** event and incrementing it in the **PrintPage** event.
PaperBin	**PaperSources** property of the **PrinterSettings** class.
PaperSize	**PaperSize** property of the **PageSettings** class.
Port	No longer necessary. The **PrintPreviewDialog** control automatically sets port information.
PrintQuality	**PrinterResolutions** property of the **PrinterSettings** class.
RightToLeft	No longer necessary. The direction of printing is controlled by the localization settings in Windows.
ScaleHeight	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.
ScaleLeft	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.
ScaleMode	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.
ScaleTop	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.
ScaleWidth	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.
TrackDefault	No direct equivalent. The **IsDefaultPrinter** property of the **PrinterSettings** class can be used to determine if a printer is the default, but printing is no longer halted if the default printer changes.
TwipsPerPixelX	No longer necessary. Measurements in Visual Basic .NET are always in pixels.
TwipsPerPixelY	No longer necessary. Measurements in Visual Basic .NET are always in pixels.
Width	**PaperSize** property of the **PageSettings** class.
Zoom	No longer necessary. If the printer has zoom capabilities, settings are automatically exposed in the Print dialog box.

Printer Methods

Visual Basic 6.0	Visual Basic .NET Equivalent
Circle	**Graphics.DrawEllipse**
EndDoc	**Print**
KillDoc	**PrintEventArgs.Cancel**
Line	**Graphics.DrawLine**
NewPage	**PrintPageEventArgs.HasMorePages**
PaintPicture	**Graphics.DrawImage**
PSet	**Graphics.DrawLine**
Scale	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.
ScaleX	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.

ScaleY	No equivalent. For details, see Coordinate System Changes in Visual Basic .NET.
TextHeight	**Font** parameter of **Graphics.DrawString**
TextWidth	**Font** parameter of **Graphics.DrawString**

Printers Collection Changes in Visual Basic .NET

In Visual Basic 6.0, the **Printers** collection was used to return information about available printers on a system. In Visual Basic .NET, the **PrintDialog** control returns information about available printers; properties for a given printer can be retrieved using the **PrinterSettings** class.

The **Printers** collection had two properties: **Item** and **Count**. These were standard collection properties; the **PrintDialog** control has no equivalent properties.

Introduction to the Windows Forms PrintDialog Component | PrinterSettings Class

RDO Data Control Changes in Visual Basic .NET

The Visual Basic 6.0 RDO Data Control was used as a mechanism for binding controls to a database using RDO. Visual Basic .NET has no equivalent for the Data Control; the data-binding architecture has changed and RDO is no longer supported. For more information, see Data Changes in Visual Basic .NET.

Things to Consider Before Upgrading | Data Changes in Visual Basic .NET

Screen Object Changes in Visual Basic .NET

In Visual Basic 6.0, the **Screen** object provided global information about your application, and in some case allowed you to set global properties. In Visual Basic .NET, there is no equivalent object, but most of the functionality can be duplicated using the .NET Framework.

The following table lists Visual Basic 6.0 properties their Visual Basic .NET equivalents. Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

Screen Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
ActiveControl	**System.Windows.Forms.Application.ActiveForm.ActiveControl**
ActiveForm	**System.Windows.Forms.Application.ActiveForm**
FontCount	No equivalent. The behavior for enumerating fonts is different. For more information, see Font Changes in Visual Basic .NET.
Fonts	**System.Drawing.FontFamilies** **Note** The behavior for enumerating fonts is different. For more information, see Font Changes in Visual Basic .NET.
Height	**System.Windows.Forms.Screen.PrimaryScreen.Bounds.Height**
MouseIcon	No equivalent. For more information, see Cannot set a custom MousePointer.
MousePointer	**System.Windows.Forms.Cursor** **Note** In Visual Basic 6.0, changing **Screen.MousePointer** changed the cursor's appearance until **Screen.MousePointer** was changed again. In Visual Basic .NET, it remains changed only until Windows messages are processed again (until the next DoEvents call or until the program's processing is done).
TwipsPerPixelX	No equivalent. In Visual Basic .NET, coordinates are in pixels and twips are not used as a unit of measurement.
TwipsPerPixelY	No equivalent. In Visual Basic .NET, coordinates are in pixels and twips are not used as a unit of measurement.
Width	**System.Windows.Forms.Screen.PrimaryScreen.Bounds.Width**

App Object Changes in Visual Basic .NET

Shape Control Changes in Visual Basic .NET

The **Shape** control in Visual Basic 6.0 has no equivalent in Visual Basic .NET. During upgrade, **Shape** controls are replaced with the Windows Forms **Label** control, with the **BorderStyle** property set to **FixedSingle**, and the **BackColor**, **Width**, and **Height** properties set to match the original control.

> **Note** It may be necessary to use the **ZOrder** method to achieve the same visual layout as the original application.

Shape controls with the **Shape** property set to 2-Oval or 3-Circle cannot be upgraded and are replaced with a **Label** control as a placeholder. You can replace the **Shape** control using the graphics functions built into the .NET Framework. For more information, see Graphics Changes in Visual Basic .NET.

Introduction to the Windows Forms TextBox Control

Timer Control Changes in Visual Basic .NET

The **Timer** control in Visual Basic 6.0 is replaced by the Windows Forms **Timer** component in Visual Basic .NET. The **Timer** component is placed in the tray instead of on the form at design time, and the behavior of the **Interval** property has changed. For more information, see Timer Interval property behavior has changed.

The following table lists Visual Basic 6.0 properties and events and their Visual Basic .NET equivalents.

Timer Properties and Events

Visual Basic 6.0	**Visual Basic .NET Equivalent**
Enabled property	**Enabled**
Index property	No equivalent property. The **Timer** is a component and cannot be a part of a control array.
Interval property	**Interval** **Note** The behavior of the **Interval** property has changed. For more information, see Timer Interval property behavior has changed.
Name property	No equivalent property. For more information, see Name Property Changes in Visual Basic .NET.
Parent property	No equivalent property. The **Timer** is a component and cannot have a parent.
Tag property	No equivalent. For more information, see Tag Property Changes in Visual Basic .NET.
Timer event	**Tick**

VBControlExtender Object Changes in Visual Basic .NET

In Visual Basic 6.0, the **VBControlExtender** object was used to provide access to properties of a host form to an ActiveX control. In Visual Basic .NET, the forms architecture is different; an extender is no longer needed.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

VBControlExtender Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
Align **0 – None** **1 – Top** **2 – Bottom** **3 – Left** **4 – Right**	**Dock** **DockStyle.None** **DockStyle.Top** **DockStyle.Bottom** **DockStyle.Left** **DockStyle.Right**
Cancel	No equivalent.
CausesValidation	**CausesValidation**
Container	**Parent**
DataBindings	No equivalent. For more information, see Data Changes in Visual Basic .NET.
DataChanged	No equivalent. For more information, see Data Changes in Visual Basic .NET.

VScrollBar Control Changes in Visual Basic .NET

The **VScrollBar** control in Visual Basic 6.0 is replaced by the Windows Forms **VScrollBar** control in Visual Basic .NET. The names of some properties, methods, events, and constants are different, and in some cases there are differences in behavior.

The following tables list Visual Basic 6.0 properties, methods, and events and their Visual Basic .NET equivalents. Where applicable, constants are indented beneath the property or method. All Visual Basic .NET constants map to the **System.Windows.Forms** namespace unless otherwise noted.

Links are provided as necessary to topics explaining differences in behavior. Where there is no direct equivalent in Visual Basic .NET, links are provided to topics that present alternatives.

VScrollBar Properties

Visual Basic 6.0	Visual Basic .NET Equivalent
CausesValidation	**CausesValidation**
Container	**Parent**
DragIcon	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
DragMode	No equivalent. For more information, see Drag and Drop Changes in Visual Basic .NET.
Enabled	**Enabled**
Height	**Height, Size** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
HelpContextID	No equivalent. For more information, see Help Support Changes in Visual Basic .NET.
HWnd	**Handle**
Index	No equivalent. For more information, see Control Array Changes in Visual Basic .NET.
LargeChange	**LargeChange** **Note** The default value in Visual Basic 6.0 was 1; in Visual Basic .NET the default value is 10.
Left	**Left** **Note** Coordinates are handled differently in Visual Basic .NET. For more information, see Coordinate System Changes in Visual Basic .NET.
Max	**Maximum** **Note** The default value in Visual Basic 6.0 was 32767; in Visual Basic .NET the default value is 100.
Min	**Minimum** **Note** In Visual Basic 6.0 **Min** could be set to a value greater than **Max**; in Visual Basic .NET this is not allowed.
MouseIcon	No equivalent. For more information, see Cannot set a custom MousePointer.
MousePointer	**Cursor** For a list of constants, see MousePointer Changes in Visual Basic .NET.
Name	**Name**
Parent	**FindForm** method
RightToLeft **True** **False**	**RightToLeft** **RightToLeft.Yes** **RightToLeft.No**

Control Property, Method, and Event Changes in Visual Basic .NET

Many of the properties, methods, and events for Visual Basic 6.0 controls and objects are replaced by Visual Basic .NET properties, methods, and events with different behavior.

The following topics describe the changes for properties, methods, and events.

In This Section

Appearance and BorderStyle Property Changes in Visual Basic .NET
Describes changes to the **Appearance** and **BorderStyle** properties of various controls.
BackStyle Property Changes in Visual Basic .NET
Describes changes to the **BackStyle** property of the **Label** control.
Change Event Changes in Visual Basic .NET
Describes changes to the **Change** event of the **ComboBox** control.
Coordinate System Changes in Visual Basic .NET
Describes changes to the **Height** and **Width** properties and the **Move** method.
Drag and Drop Changes in Visual Basic .NET
Describes changes to drag and drop properties, methods, and events.
Dynamic Data Exchange Changes in Visual Basic .NET
Describes changes to Dynamic Data Exchange (DDE).
Event Changes in Visual Basic .NET
Describes changes to event handling.
Font Changes in Visual Basic .NET
Describes changes to font handling and font properties.
Form Event Changes in Visual Basic .NET
Describes changes to various form events.
Graphics Changes in Visual Basic .NET
Describes changes to graphics properties, methods, and events.
Locked Property Changes in Visual Basic .NET
Describes changes to the **Locked** property of the **ComboBox** control.
MaxLength Property Changes in Visual Basic .NET
Describes changes to the **MaxLength** property of the **TextBox** control.
MousePointer Changes in Visual Basic .NET
Describes changes to the **MousePointer** property and constants.
Moveable Property Changes in Visual Basic .NET
Describes changes to the **Moveable** property of a form.
Name Property Changes in Visual Basic .NET
Describes changes to the **Name** property of **Timer** or **Menu** controls.
PrevInstance Property Changes in Visual Basic .NET
Describes changes to the **PrevInstance** property of the **App** object.
Style Property Changes in Visual Basic .NET
Describes changes to the **Style**, **Picture**, **Disabled Picture**, and **DownPicture** properties of various controls.
Tag Property Changes in Visual Basic .NET
Describes changes to the **Tag** property of **Timer** and **Menu** controls.
TaskVisible Property Changes in Visual Basic .NET
Describes changes to the **TaskVisible** property of the **App** object.
ToolTip Changes in Visual Basic .NET
Describes changes to the **ToolTip** property of various controls.
TopIndex Property and Scroll Event Changes in Visual Basic .NET
Describes changes to the **TopIndex** property and the **Scroll** event of **ComboBox** and **ListBox** controls.
Version Numbering Changes in Visual Basic .NET
Describes changes to the **Version** property of the **App** object.

Appearance and BorderStyle Property Changes in Visual Basic .NET

In Visual Basic 6.0, the **Appearance** and/or the **BorderStyle** properties were used to change the appearance of controls. In Visual Basic .NET, the **Appearance** property no longer exists, and the **BorderStyle** property has an additional option.

Visual Basic 6.0 forms and the Visual Basic 6.0 **Frame**, **Image**, **Label**, **PictureBox**, and **TextBox** controls supported both the **Appearance** and **BorderStyle** properties. During upgrade, the properties are mapped as follows:

Visual Basic 6.0	Visual Basic .NET
Appearance = 0 – Flat **BorderStyle = 0 – None**	**BorderStyle = BorderStyle.None**
Appearance = 0 – Flat **BorderStyle = 1 – Fixed Single**	**BorderStyle = BorderStyle.FixedSingle**
Appearance = 1 – 3D **BorderStyle = 0 – None**	**BorderStyle = BorderStyle.None**
Appearance = 1 – 3D **BorderStyle = 1 – Fixed Single**	**BorderStyle = BorderStyle.Fixed3D**

> **Note** The VisualBasic .NET **BorderStyle** constants map to the **System.Windows.Forms** namespace.

For the **Frame** control, the mappings apply only to **Frame** controls that are upgraded to **Panel** controls; there is no **BorderStyle** property for **GroupBox** controls. For more information, see Frame Control Changes in Visual Basic .NET.

The Visual Basic 6.0 **ComboBox**, **CommandButton**, and **ListBox** controls supported only the **Appearance** property. There is no equivalent for the **Appearance** property in Visual Basic .NET. During upgrade, the **Appearance** property is not mapped; if the **Appearance** property is set in code, an upgrade warning will be added.

> **Note** The Visual Basic .NET **Button** control supports the **FlatStyle** property that can be used to provide a flat appearance. The **ListBox** control can be made to appear flat by setting the **BorderStyle** property to **FixedSingle**. The **ComboBox** control never actually supported a flat appearance in Visual Basic 6.0, so there is no equivalent.

Change Event Changes in Visual Basic .NET

In Visual Basic 6.0, the **Change** event of the **ComboBox** control was raised when the text in the text-entry portion of the control was modified; it was not raised when an item was selected from the list portion of the control. Programmatically changing the text of an item in the list did not raise the **Change** event.

When a project is migrated to Visual Basic .NET, the **Change** event of the **ComboBox** control is mapped to the **TextChanged** event of the Visual Basic .NET **ComboBox** control. The behavior of the **TextChanged** event differs from that of the **Change** event; this difference may cause unintended results in your code.

The Visual Basic .NET **TextChanged** event is raised every time the text changes for any reason: when the text-entry portion is modified, when an item is selected from the list, when a list item is modified programmatically, and when the **AddItem** method is called.

The following example illustrates the behavior differences:

```
' Visual Basic 6.0
Private Sub Form_Load()
   ' Does not raise the Change event.
   Combo1.AddItem "A"
End Sub
Private Sub Form_Click()
   ' Does not raise the Change event.
   Combo1.List(0) = "B"
End If

' Visual Basic .NET
Private Sub New()
   ' Raises the TextChanged event.
   ComboBox1.Items.Add "A"
End Sub
Protected Sub Form1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs))
   ' Uses the SelectItem string method from the VB6 compatibility library
   ' because there is no equivalent method in Visual Basic .NET.
   ' Raises the TextChanged event.
   VB6.SetItemString(ComboBox1, 0, "B")
End Sub
```

What to do next

- Set a breakpoint in the **TextChanged** event procedure and run your code to determine where it is being raised. Modify your code as necessary.

ComboBox Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Coordinate System Changes in Visual Basic .NET

In Visual Basic 6.0, coordinates for forms and controls were expressed in twips; in Visual Basic .NET, coordinates are expressed in pixels. During upgrade the **Height** and **Width** properties of forms and controls are automatically converted to pixels.

Visual Basic .NET also provides a **Size** property that allows you to change both height and width in a single step. The following example shows how to change the **Size** property of a form at run time:

```
' Resizes the form to 640 pixels wide by 480 pixels high.
Me.Size = New System.Drawing.Size(640, 480)
```

Visual Basic 6.0 used the **Move** method to change the location of a form or control at run time. In Visual Basic .NET, **Move** is replaced by **SetBounds**; the coordinates are expressed in pixels. The following example demonstrates using **SetBounds** to move controls:

```
' Visual Basic 6.0
' Move and resize to 1200 by 800 twips.
CommandButton1.Move 0, 0, 1200, 800
' Move and retain original size.
CommandButton2.Move 2000, 1000
```

Visual Basic .NET equivalent

```
' Visual Basic .NET
' Move and resize to 120 by 80 pixels.
button1.SetBounds(0, 0, 120, 80)
' Move and retain original size.
button2.SetBounds(20, 10, 0, 0, BoundsSpecified.X Or BoundsSpecified.Y)
```

Visual Basic 6.0 also provided a **ScaleMode** property that allowed you to define a different coordinate system. **ScaleMode** and its related properties and methods (**Scale**, **ScaleHeight**, **ScaleLeft**, **ScaleTop**, **ScaleWidth**, **ScaleX**, **ScaleY**) are not supported in Visual Basic .NET. For more information, see ScaleMode is not supported.

Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Drag and Drop Changes in Visual Basic .NET

In Visual Basic 6.0, drag and drop could be accomplished by two different methods: standard drag and drop for dragging between controls on a form, and OLE drag and drop for dragging between forms and applications.

In Visual Basic .NET, a single model for drag and drop is used. It is similar to OLE drag and drop, but the names and parameters for drag-and-drop methods and events are different, and the event model is different. Drag-and-drop code cannot automatically be upgraded to Visual Basic .NET; it must be rewritten using the new model.

The following example shows the differences when dragging text from one **TextBox** control to another:

```
' Visual Basic 6.0
Private Sub Text1_MouseDown(Button As Integer, Shift As Integer, X As Single, Y As Single)
   Text1.Text = "Hello World"
   ' Begin dragging by calling the OLEDrag method.
   Text1.OLEDrag
End Sub

Private Sub Text1_OLEStartDrag(Data As DataObject, AllowedEffects As Long)
   ' Only allow copying.
   AllowedEffects = vbDropEffectCopy
   Data.Clear
   ' Populate the Data object with the text to copy and the format.
   Data.SetData Text1.Text, vbCFText
End Sub

Private Sub Text2_OLEDragOver(Data As DataObject, Effect As Long, Button As Integer, Shift As
Integer, X As Single, Y As Single, State As Integer)
   ' Make sure that the format is text.
   If Data.GetFormat(vbCFText) Then
      ' If it is text, enable dropping for the second TextBox.
      Text2.OLEDropMode = vbOLEDropManual
    End If
End Sub

Private Sub Text2_OLEDragDrop(Data As DataObject, Effect As Long, Button As Integer, Shift As
Integer, X As Single, Y As Single)
   ' Copy the text from the Data object to the second TextBox.
   Text2.Text = Data.GetData(vbCFText)
End Sub

' Visual Basic .NET
Private Sub Form1_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles My
Base.Load
   ' Dropping must be enabled before the dragging occurs.
   TextBox2.AllowDrop = True
End Sub

Private Sub TextBox1_MouseDown(ByVal sender As Object, ByVal e As System.Windows.Forms.MouseE
ventArgs) Handles TextBox1.MouseDown
   TextBox1.Text = "Hello World"
   ' Begin dragging by calling the DoDragDrop method.
   ' OLEStartDrag is replaced by arguments on the method.
   TextBox1.DoDragDrop(TextBox1.Text, DragDropEffects.Copy)
End Sub

Private Sub TextBox2_DragEnter(ByVal sender As Object, ByVal e As System.Windows.Forms.DragEv
entArgs) Handles TextBox2.DragEnter
' Make sure that the format is text.
If (e.Data.GetDataPresent(DataFormats.Text)) Then
      ' Allow drop.
      e.Effect = DragDropEffects.Copy
   Else
      ' Do not allow drop.
      e.Effect = DragDropEffects.None
   End If
End Sub
```

```
Private Sub TextBox2_DragDrop(ByVal sender As Object, ByVal e As System.Windows.Forms.DragEve
ntArgs) Handles TextBox2.DragDrop
   ' Copy the text to the second TextBox.
   TextBox2.Text = e.Data.GetData(DataFormats.Text).ToString
End Sub
```

Drag-and-Drop Operations and Clipboard Support

Dynamic Data Exchange Changes in Visual Basic .NET

Dynamic Data Exchange (DDE) was an early technology that enabled the exchange of information between applications in Visual Basic 3.0. DDE was replaced by OLE Automation in later versions of Visual Basic; however, DDE was still supported for backward compatibility through version 6.0.

With the introduction of Visual Basic .NET, DDE is no longer supported. Visual Basic applications that need to exchange information with legacy applications that only support DDE should be maintained in Visual Basic 6.0.

The following DDE properties, methods, and events are no longer available:

Properties

LinkItem

LinkMode

LinkTimeOut

LinkTopic

Methods

LinkExecute

LinkPoke

LinkRequest

LinkSend

Events

LinkClose

LinkError

LinkExecute

LinkNotify

LinkOpen

In addition, the **Clipboard** object constant **vbCFLink** is no longer valid.

Event Changes in Visual Basic .NET

In Visual Basic 6.0, events were tied to specific objects and had their own event-handling code. For example, on a form with a button and a menu, each had its own **Click** event; you had to write code in the event handler for each even if they both performed exactly the same function.

In Visual Basic .NET, events are tied to event handlers via delegates, allowing you to create a single event handler for multiple objects. For more information, see Introduction to Event Handlers in Windows Forms.

In addition, the names and behavior of some events for various objects are different in Visual Basic .NET. For more information, see Control Changes in Visual Basic .NET.

See Also

Event Handling in Windows Forms

Font Changes in Visual Basic .NET

Fonts in Visual Basic 6.0 were handled in two different ways: as font properties of forms and controls, or as a **stdFont** object. In Visual Basic .NET, there is a single **Font** object: **System.Drawing.Font**.

Setting Font Properties

In Visual Basic 6.0, font properties could be set at run time either by assigning a **stdFont** object or by setting the properties directly:

```
' Visual Basic 6.0
' Uses the stdFont object.
Dim f As New stdFont
' Sets the stdFont object to the Arial font.
f.Name = "Arial"
' Assigns the stdFont to the font property.
Set Label1.Font = f
' Can still change properties at run time.
Label1.FontBold = True
Label1.Font.Italic = True
```

In Visual Basic .NET, fonts are read-only at run time — you cannot set the properties directly, but you can assign a new **Font** object:

```
' Visual Basic .NET
' Fails - property is read-only.
label1.Font = Arial
' Assign a Font object — Name and Size are required.
label1.Font = New System.Drawing.Font("Arial", 10)
' Assign additional attributes.
label1.Font = New System.Drawing.Font(label1.Font, FontStyle.Bold __
    Or FontStyle.Italic)
```

Font Inheritance

In Visual Basic 6.0, font properties had to be set individually for each control or form. In Visual Basic .NET, font properties are automatically inherited from their parent unless they are explicitly set for the child object. For example, if you had two label controls on a form and changed the font properties of the form to Arial, the label control's fonts would also change to Arial. If you subsequently changed the font of one label to Times Roman, further changes to the form's font would not override the label's font.

Font Compatibility

Visual Basic 6.0 supported raster fonts for backward compatibility; Visual Basic .NET supports only TrueType and OpenType fonts. During upgrade, raster fonts are converted to the default OpenType font, Microsoft Sans Serif. Formatting such as Bold or Italic is not preserved. For more information, see Only OpenType and TrueType fonts are supported.

Enumerating Fonts

In Visual Basic 6.0, you could use the **Screen.Fonts** collection along with **Screen.FontCount** property to enumerate the available screen fonts.

In Visual Basic .NET, the **Screen** object no longer exists; in order to enumerate available fonts on the system you should use the **System.Drawing.FontFamily** namespace.

```
' Visual Basic 6.0
Dim i As Integer
For i = 0 To Screen.FontCount - 1
   List1.AddItem Screen.Fonts(i)
Next i

' Visual Basic .NET
Dim ff As FontFamily
```

```
For Each ff In System.Drawing.FontFamily.Families
   listBox1.Items.Add(ff.Name)
Next
```

Note Visual Basic 6.0 enumerated all types of fonts. Visual Basic .NET only supports TrueType and OpenType fonts; other font types will not be enumerated. In addition, Visual Basic 6.0 enumerated each character set version within a font family (for instance, Arial, Arial Baltic, Arial Greek); Visual Basic .NET enumerates the font families.

Font Class | FontFamily.Families Property | Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Form Event Changes in Visual Basic .NET

There are some differences in form event behavior between Visual Basic 6.0 and Visual Basic .NET.

In Visual Basic 6.0, the **Initialize** event was used to execute code before a form was loaded. In Visual Basic .NET, initialization code must be added to the form constructor (**Sub New()**) after the call to **InitializeComponent()** as in the following example:

```
' Visual Basic 6.0
Private Sub Form_Initialize()
    frmSplash.Show
End Sub

' Visual Basic .NET
Public Sub New()
    MyBase.New()
    ' This call is required by the Windows Forms Designer.
    InitializeComponent()
    ' Add your initialization code here.
    FrmSplash.Show()
End Sub
```

In Visual Basic 6.0, the **Terminate** event was used to execute code after a form was unloaded. In Visual Basic .NET, the **Terminate** event is no longer supported. Termination code must be executed inside the **Dispose** method, before the call to **MyBase.Dispose()**.

> **Note** The **Dispose** method is called automatically for the main form in an application; you need to call it explicitly for any other form.

The following example demonstrates the differences. Note that a static variable is used to prevent the termination code from executing twice — this is necessary because the **Dispose** method is public and might be called outside of the form's code.

```
' Visual Basic 6.0
Private Sub Form_Terminate()
    MsgBox "The form was terminated"
End Sub

' Visual Basic .NET
Public Overrides Sub Dispose(ByVal Disposing As Boolean)

    Static fTerminated As Boolean
    If Not fTerminated Then
        Form_Terminate
        fTerminated = True
    End If
    ' The following code was automatically added by the Dispose method.
    MyBase.Dispose(Disposing)
    If Disposing Then
        If Not components Is Nothing Then
            Components.Dispose(Disposing)
        End If
    End If
End Sub
```

In Visual Basic 6.0, the **Unload** event had a Cancel argument; in Visual Basic .NET, it is replaced by the **Closed** event, which does not have a Cancel argument. If you need to cancel during unloading, use the **Closing** event instead.

In Visual Basic 6.0, MDI Forms supported mouse events. In Visual Basic .NET, the **Click**, **MouseDown**, **MouseMove**, and **MouseUp** events are no longer supported for MDI Forms, since the MDI Form has no client area to receive mouse events.

See Also

Form Object Changes in Visual Basic .NET | Form Constructor | Form.Closing Event

Graphics Changes in Visual Basic .NET

In Visual Basic 6.0, various graphics methods and properties were used to draw on a form or **PictureBox** control. Graphics in Visual Basic 6.0 were based on Windows Graphics Device Interface (GDI) APIs.

In Visual Basic .NET, graphics are provided by the **System.Drawing** namespace, which encapsulates the new GDI+ APIs. GDI+ expands upon the graphics capabilities of Visual Basic 6.0, but the methods are not compatible. When an application is upgraded from Visual Basic 6.0, graphics methods are not upgraded.

The following example shows the code used to draw a circle in the upper left corner of a form using Visual Basic 6.0 and Visual Basic .NET:

```
' Visual Basic 6.0
Private Sub Form_Click()
   ' Set the ScaleMode to pixels.
   Me.ScaleMode = 3
   Me.Circle (50, 50), 50, vbRed
End Sub

' Visual Basic .NET
Private Sub Form1_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles MyBase.C
lick
   ' Create a Pen object.
   Dim pen As New Drawing.Pen(System.Drawing.Color.Red, 1)
   Me.CreateGraphics.DrawEllipse(pen, 0, 0, 100, 100)
   Pen.Dispose
End Sub
```

The following table lists Visual Basic 6.0 graphics properties and methods and their Visual Basic .NET equivalents.

Visual Basic 6.0	**Visual Basic .NET Equivalent**
AutoRedraw Property	No equivalent. To persist graphics, put graphics methods in the **Paint** event.
Circle Method	Graphics.DrawEllipse Method
ClipControls Property	No equivalent. To repaint only part of an object, create a clip in the **Paint** event using the Graphics.SetClip Method method.
Cls Method	Graphics.Clear Method
CurrentX Property	The ***x*** parameter of various graphics methods. For example, DrawRectangle(pen, ***x***, y, width, height)
CurrentY Property	The ***y*** parameter of various graphics methods. For example, DrawRectangle(pen, x, ***y***, width, height)
DrawMode Property	Pen.Color Property
DrawStyle Property	Pen.PenType Property
DrawWidth Property	Pen.Width Property
FillColor Property	SolidBrush.Color Property
FillStyle Property	Pen.Brush Property
HasDC Property	No equivalent. Device contexts are no longer necessary with GDI+.
HDC Property	No equivalent. Device contexts are no longer necessary with GDI+..
Image Property	**Image** Property. In Visual Basic 6.0 the **Image** property returned a handle; in Visual Basic .NET it returns a **System.Drawing.Image** object.
Line Method	Graphics.DrawLine Method
PaintPicture Method	Graphics.DrawImage Method
Point Method	No equivalent for forms or controls. For bitmaps, use Bitmap.GetPixel Method.
Print Method	Graphics.DrawString Method
Pset Method	No equivalent for forms or controls. For bitmaps, use Bitmap.SetPixel Method.

TextHeight Property	Font.Height Property
TextWidth Property	Graphics.MeasureString Method

Creating Graphical Images with GDI+

MaxLength Property Changes in Visual Basic .NET

In Visual Basic 6.0, the **MaxLength** property of a **TextBox** control had absolute control over the length of a string that could be entered or displayed in the text box. Although you could programmatically enter a longer string, it would automatically be truncated to the length set in the **MaxLength** property.

In Visual Basic .NET, the length of a string entered programmatically will override the **MaxLength** property setting.

The following code illustrates the different behavior.

```
' Visual Basic 6.0
Text1.MaxLength = 5
Text1.Text = "Longer than five"
MsgBox Text1.Text       ' Displays "Longe".

' Visual Basic .NET
Text1.MaxLength = 5
Text1.Text = "Longer than five"
MsgBox Text1.Text       ' Displays "Longer than five".
```

What to do next

- Review the design of your application to determine if the intended behavior was to always limit the text in the text box to the length set in the **MaxLength** property.
  - If this was the intended behavior, find each occurrence of code that sets the **Text** property and add code to truncate the string similar to the following example.

    ```
    ' Old code
    Text1.Text = SomeString

    ' Replacement code
    If Len(SomeString) > Text1.MaxLength Then
       SomeString = Left(SomeString, Text1.MaxLength)
    End If

    Text1.Text = SomeString
    ```

  - If it was not the intended behavior, leave the code alone. The user will still be limited by the **MaxLength** setting, but you can programmatically assign strings that are longer than the **MaxLength** setting.

TextBox Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

MousePointer Changes in Visual Basic .NET

In Visual Basic .NET, the **MousePointer** property has been replaced by the **Cursor** property, and the names of the **MousePointer** constants have changed.

Visual Basic 6.0 allowed you to use a bitmap as a custom **MousePointer**; this is no longer supported in Visual Basic .NET. You can set a custom **Cursor** at run time by assigning a cursor file:

```
' Visual Basic .NET
button1.Cursor = New System.Windows.Forms.Cursor("C:\mypath\mycursor.cur")
```

In addition, the icon MousePointer (vbIconPointer) is obsolete and is replaced by the default cursor during upgrade.

MousePointer Constant Equivalents

Visual Basic 6.0	Visual Basic .NET Equivalent
0 – vbDefault	**System.Windows.Forms.Cursors.Default**
1 – vbArrow	**System.Windows.Forms.Cursors.Arrow**
2 – vbCrossHair	**System.Windows.Forms.Cursors.Cross**
3 – vbIBeam	**System.Windows.Forms.Cursors.IBeam**
4 – vbIconPointer	Obsolete — replaced by **System.Windows.Forms.Cursors.Default**
5 – vbSizePointer	**System.Windows.Forms.Cursors.SizeAll**
6 – vbSizeNESW	**System.Windows.Forms.Cursors.SizeNESW**
7 – vbSizeNS	**System.Windows.Forms.Cursors.SizeNS**
8 – vbSizeNWSE	**System.Windows.Forms.Cursors.SizeNWSE**
9 – vbSizeWE	**System.Windows.Forms.Cursors.SizeWE**
10 – vbUpArrow	**System.Windows.Forms.Cursors.UpArrow**
11 – vbHourGlass	**System.Windows.Forms.Cursors.WaitCursor**
12 – vbNoDrop	**System.Windows.Forms.Cursors.No**
13 – vbArrowHourGlass	**System.Windows.Forms.Cursors.AppStarting**
14 – vbArrowQuestion	**System.Windows.Forms.Cursors.Help**
15 – vbSizeAll	**System.Windows.Forms.Cursors.SizeAll**
99 – vbCustom	No equivalent — for more information, see Cannot set a custom MousePointer

Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Moveable Property Changes in Visual Basic .NET

In Visual Basic 6.0, the **Moveable** property of a form could be set to **false** to prevent a user from moving the form at run time. Windows Forms in Visual Basic .NET do not have an equivalent property.

Although it is generally considered bad user interface design, you can achieve similar behavior in Visual Basic .NET by setting the **Form.FormBorderStyle** property to **none** and the **Form.ControlBox** property to **false.**

See Also

Form Object Changes in Visual Basic .NET | MDIForm Object Changes in Visual Basic .NET | Form.ControlBox Property

Style Property Changes in Visual Basic .NET

In Visual Basic 6.0, setting the **Style** property of a **CommandButton**, **CheckBox** or **OptionButton** control to **1 – Graphical** changed the appearance of the control to display images. The **Picture**, **DownPicture**, and **DisabledPicture** properties were used to assign images to be displayed in response to state changes. For example, when a **CheckBox** control was checked, the **DownPicture** image was displayed; if the control was disabled, the **DisabledPicture** image was displayed.

Visual Basic .NET no longer supports the **Style**, **Picture**, **DownPicture**, or **DisabledPicture** properties. The **Style** property is replaced by the **Appearance** property, the **Picture** property is replaced by the **Image** property, and the functionality of the **DownPicture** and **DisabledPicture** properties can be emulated using an **ImageList** control.

When an application is upgraded to Visual Basic .NET, if the **Style** property is set to **1 – Graphical**, the **Appearance** property of the upgraded control is set to **Button**, and any image assigned to the **Picture** property at design time is assigned to the **Image** property of the upgraded control.

What to do next

- Check your Visual Basic 6.0 application. If the **DownPicture** and **DisabledPicture** properties are not being set at design time or at run time, the behavior should be the same in Visual Basic .NET.
- If the **DownPicture** or **DisabledPicture** properties are being set, take the following steps to modify the upgraded application:

  Note The following example uses a **CheckBox** control; the same steps apply for an **OptionButton** control (replaced by **RadioButton** control in Visual Basic .NET).

  - Determine the file names and locations of the images that were assigned to the **Picture**, **DownPicture**, and **DisabledPicture** properties and, if necessary, copy them to your development computer.
  - Add an **ImageList** control from the Toolbox to your form.
  - In the Properties window, select the **Images** property.
  - In the Image Collection Editor, add the images for the **Picture**, **DownPicture**, and **DisabledPicture** properties, in that order.
  - If any of the properties were set at run time, remove the code.
  - If the properties were set a design time, add the following code to the **Load** event for the form:

    ```
    ' Assign the first image (Picture) to the Image property.
    checkBox1.Image = imageList1.Images(0)
    ```

  - To display the **DownPicture** image at run time, add the following code to the **CheckChanged** event for the **CheckBox** control:

    ```
    If checkBox1.Checked = True Then
       ' Assign the second image (DownPicture) to the Image property.
       checkBox1.Image = imageList1.Images(1)
    Else
       ' Assign the first image (Picture) to the Image property.
       checkBox1.Image = imageList1.Images(0)
    End If
    ```

  - To display the **DisablePicture** image at run time, add the following code to the **EnabledChanged** event for the **CheckBox** control:

    ```
    If checkBox1.Enabled = False Then
       ' Assign the third image (DisabledPicture) to the Image property.
       checkBox1.Image = imageList1.Images(2)
    ElseIf checkBox1.Checked = True Then
       ' Assign the second image (DownPicture) to the Image property
       checkBox1.Image = imageList1.Images(1)
    Else
       ' Assign the first image (Picture)to the Image property
       checkBox1.Image = imageList1.Images(0)
    ```

```
End If
```

The application should now behave exactly as it did in Visual Basic 6.0.

ToolTip Changes in Visual Basic .NET

In Visual Basic 6.0, the **ToolTipText** property of a control was used to display a ToolTip at run time. If the property contained text, the ToolTip was displayed; if it was empty, no ToolTip was displayed.

In Visual Basic .NET, a single **ToolTip** control can be used to control the ToolTips for all controls on a form. The **SetToolTip** method is used to set the text for each ToolTip.

The following example demonstrates setting a ToolTip in Visual Basic 6.0 and Visual Basic .NET:

```
' Visual Basic 6.0
Button1.ToolTipText = "Saves changes"

' Visual Basic .NET
' Adds a ToolTip control (ToolTip1) to the form.
ToolTip1.SetToolTip(Button1, "Save changes")
```

See Also

Control Changes in Visual Basic .NET

TopIndex Property and Scroll Event Changes in Visual Basic .NET

In Visual Basic 6.0, the **TopIndex** property was used to return or set a value that specifies which item in a **ComboBox** or **ListBox** control is displayed in the topmost position. This property was commonly used to scroll the list without selecting an item.

In Visual Basic .NET, the **ComboBox** control no longer supports the **TopIndex** property. In most cases this should not present a problem, because setting the **TopIndex** property had no visible effect unless the **Style** property was set to **1 - SimpleCombo**. In this case, you can emulate the **ComboBox** SimpleCombo behavior by using a **ListBox** control and a **TextBox** control; the **ListBox** control still supports the **TopIndex** property.

The **Scroll** event in Visual Basic 6.0 was used in conjunction with the **TopIndex** property to perform actions when the list was scrolled. Visual Basic .NET does not support the **Scroll** event; however, in most cases the **SelectedIndexChanged** event should be a suitable replacement.

See Also

ComboBox Control Changes in Visual Basic .NET | ListBox Control Changes in Visual Basic .NET | ComboBox.SelectedIndexChanged Event | ListBox.SelectedIndexChanged Event | UserControl Changes in Visual Basic .NET

Version Numbering Changes in Visual Basic .NET

In Visual Basic 6.0, setting the **Major**, **Minor**, and **Revision** properties of the **App** object controlled the version number for an application. For example, setting **Major** to 1, **Minor** to 2, and **Revision** to 3 resulted in a version number of 1.2.0.3.

In Visual Basic .NET, the version number properties are replaced by the **AssemblyVersion** attribute, which has four parts: **Major**, **Minor**, **Revision**, and **Build**. For the above example, the resulting version number would be 1.2.3.*x*, where *x* is a build number that is incremented each time the assembly is built.

When an application is upgraded from Visual Basic 6.0, only the **Major** and **Mino**r properties are upgraded; Visual Basic .NET assigns new values for the **Revision** and **Build** properties.

App Object Changes in Visual Basic .NET | Attributes

Control Array Changes in Visual Basic .NET

In Visual Basic 6.0, control arrays could be used to specify a group of controls that shared a set of events. The controls had to be of the same type, and they had to have the same name.

In Visual Basic .NET, control arrays are no longer supported. Changes to the event model make control arrays unnecessary. Just as control arrays in Visual Basic 6.0 could share events, the event model in Visual Basic .NET allows any event handler to handle events from multiple controls. In effect, this allows you to create groups of controls of disparate types that share the same events.

For example, you might add two **Button** controls (Button1 and Button2) and a **CheckBox** control (CheckBox1) to a form, then create an event handler to handle the **Click** event for all three controls:

```
Private Sub MixedControls_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) H
andles Button1.Click, Button2.Click, CheckBox1.Click
```

Another feature of Visual Basic 6.0 control arrays was the ability to reference a control by its **Index** property. Although Visual Basic .NET controls do not have an **Index** property, you can duplicate the functionality using another common property such as the **TabIndex** or **Tag** property.

For example, you might set the **TabIndex** property for a group of controls using the new visual tab ordering capabilities of Windows Forms, and then use the **TabIndex** in a **Select Case** statement:

```
Private Sub MixedControls_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) H
andles Button1.Click, Button2.Click, CheckBox1.Click
   Select Case sender.TabIndex
      Case 0
         MsgBox("Button 1")
      Case 1
         MsgBox("Button 2")
      Case 2
         MsgBox("CheckBox 1")
   End Select
End Sub
```

Form Positioning Changes in Visual Basic .NET

In Visual Basic 6.0, the initial screen location for a form could be set at design time using the Form Layout window or by setting the **Left** and **Top** properties in the Properties window. The **Left** and **Top** properties could also be set programmatically.

In Visual Basic .NET, the initial screen location is set at design time by setting the **Location** property, or programmatically by setting the **Location** property to a **Point** object.

In addition, Visual Basic 6.0 supported a **StartUpPosition** property that could be used to allow Windows to automatically set a location (for example, centered on the screen). The default setting was **Manual**, meaning that the **Left** and **Top** properties took precedence.

In Visual Basic .NET, the **StartPosition** property performs the same function. The default setting is now **WindowsDefaultLocation**, meaning that the **Location** property is ignored.

See Also

Setting the Screen Location of Windows Forms

Menu Changes in Visual Basic .NET

In Visual Basic 6.0, menus were created using the Menu Editor. Menus could not be created programmatically, but could be changed or added to programmatically.

In Visual Basic .NET, menus are created using **MainMenu** controls, which provide a graphical menu designer. Menus can also be created programmatically. For more information, see Menus in Windows Forms.

In Visual Basic 6.0, context menus were created by calling the **PopupMenu** method of a form or control. They could not be created programmatically; the **PopupMenu** method required that a menu already existed.

In Visual Basic .NET, context menus are created using **ContextMenu** controls; they can also be created programmatically. For more information, see Context Menus on Windows Forms.

In Visual Basic 6.0, the **NegotiateMenus** property of a form determined whether a menu from an object on the form would be merged with the form's menu. This property could only be set at design time.

In Visual Basic .NET, menus can be merged using the **MergeMenu** method of a **MainMenu** or **ContextMenu** control. For more information, see Merging Menu Items Programmatically.

See Also

Menu Object Changes in Visual Basic .NET | Menus and Context Menus | Forms Changes in Visual Basic .NET

MDI Changes in Visual Basic .NET

In Visual Basic 6.0, multiple-document interface (MDI) applications were created by adding an MDI form to a project and setting the **MDIChild** property of any child forms. In Visual Basic .NET, any form can be made an MDI parent by setting the **IsMdiContainer** property to **true**.

Properties and methods that applied to Visual Basic 6.0 MDI forms have changed in Visual Basic .NET. For more information, see MDIForm Object Changes in Visual Basic .NET.

The behavior of MDI applications has also changed. In Visual Basic 6.0, an MDI application that also contained a form that was not an MDI child would not end until that form was closed, even if the MDI parent was closed. In Visual Basic .NET, the application will end when the startup form is closed, regardless of any non-MDI forms in the application.

See Also

Multiple-Document Interface (MDI) Applications | Forms Changes in Visual Basic .NET |
Introduction to Visual Basic .NET for Visual Basic Veterans

Dialog Box Changes in Visual Basic .NET

In Visual Basic 6.0, a form could be displayed as a modal dialog box by calling the **Show** method with a parameter of **vbModal**.

In Visual Basic .NET, the **ShowDialog** method is used to display a form modally; the **Show** method is used to display a form non-modally.

In addition, the Visual Basic 6.0 **CommonDialog** control provided several predefined dialog boxes. In Visual Basic .NET, this control is replaced by the **ColorDialog** control, the **FontDialog** control, the **OpenFileDialog** control, the **PageSetupDialog** control, the **PrintDialog** control, the **PrintPreviewDialog** control, and the **SaveFileDialog** control.

See Also

Dialog Boxes in Windows Forms | Dialog-Box Controls and Components (Windows Forms)

Color Changes in Visual Basic .NET

In Visual Basic 6.0, colors were represented by a value of type **Long**; in Visual Basic .NET colors are of type **System.Drawing.Color**. When a Visual Basic 6.0 application is upgraded, colors are converted using the **System.Drawing.ColorTranslator.FromOle** class.

In Visual Basic 6.0, constants were provided for the eight standard colors as well as for system colors that could be used to map a color to the user's system preferences. In Visual Basic .NET, the system colors are of type **System.Drawing.SystemColors**.

Color Constant Equivalents

System Color Constant Equivalents

Translating Colors

Color Constant Equivalents

Visual Basic 6.0	Visual Basic .NET Equivalent
vbBlack	System.Drawing.Color.Black
vbRed	System.Drawing.Color.Red
vbGreen	System.Drawing.Color.Lime
vbYellow	System.Drawing.Color.Yellow
vbBlue	System.Drawing.Color.Blue
vbMagenta	System.Drawing.Color.Magenta
vbCyan	System.Drawing.Color.Cyan
vbWhite	System.Drawing.Color.White

System Color Constant Equivalents

Visual Basic 6.0	Visual Basic .NET Equivalent
vb3DDKShadow	System.Drawing.SystemColors.ControlDarkDark
vb3DFace	System.Drawing.SystemColors.Control
vb3DHighlight	System.Drawing.SystemColors.ControlLightLight
vb3DLight	System.Drawing.SystemColors.ControlLight
vb3DShadow	System.Drawing.SystemColors.ControlDark
vbActiveBorder	System.Drawing.SystemColors.ActiveBorder
vbActiveTitleBar	System.Drawing.SystemColors.ActiveCaption
vbActiveTitleBarText	System.Drawing.SystemColors.ActiveCaptionText
vbApplicationWorkspace	System.Drawing.SystemColors.AppWorkspace
vbButtonFace	System.Drawing.SystemColors.Control
vbButtonShadow	System.Drawing.SystemColors.ControlDark
vbButtonText	System.Drawing.SystemColors.ControlText
vbDesktop	System.Drawing.SystemColors.Desktop
vbGrayText	System.Drawing.SystemColors.GrayText
vbHighlight	System.Drawing.SystemColors.Highlight
vbHighlightText	System.Drawing.SystemColors.HighlightText
vbInactiveBorder	System.Drawing.SystemColors.InactiveBorder
vbInactiveCaptionText	System.Drawing.SystemColors.InactiveCaptionText
vbInactiveTitleBar	System.Drawing.SystemColors.InactiveCaption
vbInactiveTitleBarText	System.Drawing.SystemColors.InactiveCaptionText
vbInfoBackground	System.Drawing.SystemColors.Info
vbInfoText	System.Drawing.SystemColors.InfoText
vbMenuBar	System.Drawing.SystemColors.Menu
vbMenuText	System.Drawing.SystemColors.MenuText
vbScrollBars	System.Drawing.SystemColors.Scrollbar
vbTitleBarText	System.Drawing.SystemColors.ActiveCaptionText
vbWindowBackground	System.Drawing.SystemColors.Window
vbWindowFrame	System.Drawing.SystemColors.WindowFrame

vbWindowText	**System.Drawing.SystemColors.WindowText**

Translating Colors

To find an equivalent value for a Visual Basic 6.0 color that is not covered by the color constants, you can use the **System.Drawing.ColorTranslator** class.

The following example sets the **BackColor** property of a **TextBox** control to match the lightest green (&H00C0FFC0) from the Visual Basic 6.0 color picker:

```
' Visual Basic .NET
textBox1.BackColor = System.Drawing.ColorTranslator.FromOle(&H00C0FFC0)
```

See Also

Color Behavior Changes in Visual Basic .NET | Palette Changes in Visual Basic .NET | MaskColor Changes in Visual Basic .NET | Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Color Behavior Changes in Visual Basic .NET

In Visual Basic 6.0, the **BackColor** and **ForeColor** properties of a control had to be explicitly set at design time or at run time; colors could not be inherited. In Visual Basic .NET, unless a color is explicitly set at design time or at run time, it will inherit the color setting of its parent.

The following example of a form with two **CommandButton** controls, Command1 and Command2, demonstrates the differences in behavior:

```
' Visual Basic 6.0
' Command1's BackColor is left at its default (gray).
' Command2's BackColor is explicitly set.
Command2.BackColor = vbBlack
' Explicitly set the BackColor of the form.
Form1.BackColor = vbRed
```

After running the above code, the Command1's BackColor is still the default (gray), and Command2's BackColor is black.

The following example shows the behavior in Visual Basic .NET. In Visual Basic .NET, **CommandButton** controls are replaced by **Button** controls.

```
' Visual Basic .NET
' Command1's BackColor is left at its default (gray).
' Command2's BackColor is explicitly set.
Command2.BackColor = System.Drawing.Color.Black
' Explicitly set the BackColor of the form.
Me.BackColor = System.Drawing.Color.Red
```

After running the above code, the Command1's **BackColor** is red, and Command2's **BackColor** is black. Because the **BackColor** was not explicitly set for Command1, the color is inherited from the form.

Note that this will apply for any parent, not just forms. If the **Button** was contained in a **Panel** control within the form, changing the color of either the panel or the form would change the color of the **Button**.

What to do next

- Search for any code that explicitly sets the **BackColor** or **ForeColor** property at run time. If it is being set for a parent, explicitly set the color of the child controls at design time.

See Also

Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Palette Changes in Visual Basic .NET

In Visual Basic 6.0, the **Palette** and **PaletteMode** properties of a form were used to control the set of colors to be used when displaying images on a 256-color display.

> **Note** These properties had no effect on displays that support more than 256 colors.

Visual Basic .NET does not support the **Palette** or **PaletteMode** properties. Where Visual Basic 6.0 required a single palette per form, Visual Basic .NET supports a separate palette for each object. Palettes in Visual Basic .NET are set using the **Image.Palette** property in the **System.Drawing** namespace.

See Also

Form Object Changes in Visual Basic .NET | Image.Palette Property

MaskColor Changes in Visual Basic .NET

In Visual Basic 6.0, the **MaskColor** property of a **CheckBox**, **CommandButton**, or **OptionButton** control was used to define a color that would become transparent, allowing a background image to show through. In order to use this property, the **Style** property had to be set to **Graphical**, the **UseMaskColor** property had to be set to **true**, and a bitmap had to be assigned to the **Picture** property.

In Visual Basic .NET, there is no direct equivalent for the **MaskColor** property. You can, however, set transparency on a control using code similar to the following:

```
' Assumes a picture has been assigned to the BackgroundImage property.
Dim g As New System.Drawing.Bitmap(Button1.BackGroundImage)
g.MakeTransparent(System.Drawing.Color.White)
Button1.BackgroundImage = g
```

See Also

CheckBox Control Changes in Visual Basic .NET | CommandButton Control Changes in Visual Basic .NET | OptionButton Control Changes in Visual Basic .NET

Help Support Changes in Visual Basic .NET

In Visual Basic 6.0, Help support was implemented on a per-project basis by specifying a Help file name in the Project Properties dialog box. Each form and control had a **HelpContextID** property that was used to link to a specific topic in the Help file.

In Visual Basic .NET, Help support is implemented on a per-form basis by adding one or more **HelpProvider** components to a form. Each form and control has **HelpKeyword** and **HelpNavigator** properties that are used to link to a specific topic. For more information, see Providing Help in a Windows Application.

> **Note** In Visual Basic 6.0, Help could be provided using either HTML Help or the older Windows Help format. In Visual Basic .NET, only HTML Help is supported.

In Visual Basic 6.0, pop-up Help was implemented using the **WhatsThisButton** and **WhatsThisHelp** properties of a form. The What's This button appeared if **WhatsThisButton** was **true** and either the **MaxButton** or **MinButton** property was **false**. Setting the **WhatsThisMode** property in code enabled the button.

In Visual Basic .NET, pop-up Help is implemented using the **HelpButton** property of a form. The Help button only appears if the **HelpButton** property is set to **true** and both the **MaximizeBox** and **MinimizeBox** properties are set to **false**; the button is automatically enabled. For more information, see Displaying Pop-up Help.

In Visual Basic 6.0, ToolTips were implemented using the **ToolTipText** property of a control. In Visual Basic .NET, ToolTips are implemented by adding a **ToolTip** component to a form. For more information, see ToolTip Changes in Visual Basic .NET.

Application Assistance

Printing Changes in Visual Basic .NET

Visual Basic .NET provides greatly improved support for printing through classes that control the printing of documents, that allow users to modify print settings and choose printers, and that allow print preview.

Printer Object Changes

In Visual Basic 6.0, the **Printer** object was used for printing; it supported various graphics methods such as **Print**, **Line**, and **PaintPicture** to control what was printed.

In Visual Basic .NET, the **PrintDocument** component replaces the **Printer** object. Equivalent graphics methods include the **DrawString**, **DrawLine**, and **DrawImage** methods of the **Graphics** class.

For details, see Printer Object Changes in Visual Basic .NET.

Printers Collection Changes

In Visual Basic 6.0, the **Printers** collection was used to direct the output of a **Printer** object to a different printer. The **Printers** collection contained a list of available printers that matched the list displayed in the Windows Print dialog box.

In Visual Basic .NET, the **Printers** collection is replaced by the **PrintDialog** control, which provides a standard Windows Print dialog box.

For details, see Printers Collection Changes in Visual Basic .NET.

Other Printing Changes

In Visual Basic 6.0, the **PrintForm** method of a form could be used to send an image of the form to a printer. The **PrintForm** method is no longer supported in Visual Basic .NET. The results of the **PrintForm** method varied greatly depending on the screen resolution and the resolution of the printer; it was not the recommended method of printing. If you need to duplicate the functionality of the **PrintForm** method, you can automate the screen capture capabilities of a third-party graphics tool to capture and print an image of a form.

In Visual Basic 6.0, implementing print preview was only possible through third-party controls. In Visual Basic .NET, the **PrintPreviewDialog** control can be used to provide a standard Windows Print Preview dialog box. For more information, see Introduction to the Windows Forms PrintPreviewDialog Control.

In Visual Basic 6.0, no user interface for page setup was provided. In Visual Basic .NET, the **PageSetupDialog** control can be used to provide a standard Windows Page Setup dialog box. For more information, see Introduction to the Windows Forms PageSetupDialog Component.

In Visual Basic 6.0, printing text from a file required a considerable amount of code. In Visual Basic .NET, the **StreamReader** class can be used to pass the contents of a text file directly to a **PrintDocument** component. For details, see PrintDocument.Print Method.

See Also

Windows Forms Print Support | Printer Object Changes in Visual Basic .NET | Printers Collection Changes in Visual Basic .NET

Debugging Changes in Visual Basic .NET

Although the process of debugging an application in Visual Basic .NET is essentially the same as it was in Visual Basic 6.0, there are a few differences you will want to be aware of. In addition, there are several new features related to debugging in Visual Basic .NET. For more information, see What's New in the Visual Studio Debugger.

In Visual Basic 6.0, in most cases you could make changes to your code while in break mode and continue debugging without stopping and restarting. In Visual Basic .NET, any code changes in break mode require that the project be rebuilt before the code changes can take effect; edit and continue is no longer supported. For more information, see Limitations of Edit and Continue.

In Visual Basic 6.0, syntax errors in code would cause an error message dialog box to be displayed during debugging. In Visual Basic .NET, most syntax errors appear in the Task List window at design-time; run-time exceptions appear in the Output window. For more information, see Debugging Basics.

Some of the keyboard shortcuts for debugging are different in Visual Basic .NET. For example, in Visual Basic 6.0 the F8 command was used to step into code; in Visual Studio .NET the F11 command performs the same function. For more information, see Integrated Development Environment Changes in Visual Basic .NET.

In Visual Basic 6.0, expressions could be evaluated and values could be set in the **Immediate** window. In Visual Basic .NET, the **Command** window replaces the **Immediate** window; when in **Immediate** mode, the functionality is the same. Visual Basic .NET also supports several new options for expressions. For more information, see Expressions in Visual Basic.

Setup and Deployment Changes in Visual Basic .NET

In Visual Basic 6.0, the Package and Deployment Wizard was used to create Setup programs to distribute your application. You could also package applications or components in CAB files for Internet download.

In Visual Basic .NET, Deployment projects are used to create Windows Installers for managed installation. Components can be packaged in redistributable merge modules, and the creation of CAB files is also supported.

> **Note** Later releases of Visual Studio 6.0 included the Visual Studio Installer add-in, which could be used to create Windows Installers. Installer projects created with Visual Studio Installer are not compatible with Visual Basic .NET.

Deploying Applications and Components

International Changes in Visual Basic .NET

In Visual Basic 6.0, international versions of an application were created by putting all localizable information such as strings into a separate resource file (.res) for each language. At run time, locale-specific resources were loaded from the resource file by calling the **LoadResString**, **LoadResPicture**, and **LoadResData** functions.

In Visual Basic .NET, international versions of an application are created by changing the **Language** property of a form at design time. A separate .NET resource file (.resx) is automatically created for each locale selected. You no longer need to explicitly load resources from code; resources are automatically loaded based on the user's locale. For more information, see Globalizing Windows Forms.

> **Note** Visual Basic 6.0 resource files could be edited using the Resource Editor add-in or the Visual C++ resource editors. Visual Basic .NET resource files cannot be edited directly; instead, you must edit the properties in the IDE.

In Visual Basic 6.0, strings were represented internally as Unicode characters but were displayed using Windows code pages. The **StrConv** function along with Binary and Unicode versions of string manipulation functions (for example, **ChrB** and **ChrW**) were necessary to convert between ANSI and DBCS code pages.

In Visual Basic .NET, forms are entirely Unicode-enabled; conversion between code pages is no longer required. For more information, see Encoding and Windows Forms Globalization.

In Visual Basic 6.0, the formatting of dates and currency in code required special consideration; values entered as text could be incorrectly interpreted when converted to dates or currency in localized applications.

In Visual Basic .NET, dates and currency are automatically formatted according to the user's culture. You can override the settings if necessary through functions in the **System.Globalization** namespace. For more information, see Culture-Specific Classes for Global Windows Forms and Web Forms.

Windows API Changes in Visual Basic .NET

In Visual Basic 6.0, the **Declare** statement was used to call the Windows API in order to access functionality not provided by Visual Basic. In Visual Basic .NET, the need to access the Windows API is greatly diminished because much of the functionality of the Windows API is wrapped up in the .NET Framework.

The **Declare** statement can still be used to call an API, but there are some differences that you need to be aware of. For example, some of the data types in Visual Basic .NET have no direct equivalent; they must be marshaled in order to be passed to an API call. For more information, see Walkthrough: Calling Windows APIs.

Registry Access Changes in Visual Basic .NET

In Visual Basic 6.0, you could access the registry using the **GetSetting** or **SaveSetting** functions, which provided access to a limited set of registry keys. To access other registry keys, calls to the Windows API were required.

In Visual Basic .NET, the **GetSetting** and **SaveSetting** functions are still supported for limited registry access. For more information, see Registry Summary.

In addition, complete access to the registry is provided via the **Registry** class in the .NET Framework.

In Visual Basic 6.0, files could be marked for registration during installation by manually editing the Setup.lst file. In Visual Basic .NET, the deployment tools provide full support for working with the registry during installation. For more information, see Deployment and the Registry.

Constant Changes in Visual Basic .NET

In Visual Basic 6.0, numerous constants were defined in the Visual Basic language. In Visual Basic .NET, most of the constants are replaced by enumerations in the .NET Framework.

The following links will take you to topics that show the mappings between Visual Basic 6.0 constants and their Visual Basic .NET equivalents.

> **Note** If a constant is not listed, there is no equivalent. For example, DDE constants are not listed because DDE is not supported in Visual Basic .NET.

vbKeyScrollLock (145)	System.Windows.Forms.Keys.Scroll

Alphabetic Key Code Constants

Visual Basic 6.0	Visual Basic .NET Equivalent
VbKeyA (65)	System.Windows.Forms.Keys.A
VbKeyB (66)	System.Windows.Forms.Keys.B
VbKeyC (67)	System.Windows.Forms.Keys.C
VbKeyD (68)	System.Windows.Forms.Keys.D
VbKeyE (69)	System.Windows.Forms.Keys.E
VbKeyF (70)	System.Windows.Forms.Keys.F
VbKeyG (71)	System.Windows.Forms.Keys.G
VbKeyH (72)	System.Windows.Forms.Keys.H
VbKeyI (73)	System.Windows.Forms.Keys.I
VbKeyJ (74)	System.Windows.Forms.Keys.J
VbKeyK (75)	System.Windows.Forms.Keys.K
VbKeyL(76)	System.Windows.Forms.Keys.L
vbKeyM (77)	System.Windows.Forms.Keys.M
VbKeyN (78)	System.Windows.Forms.Keys.N

VbKeyO (79)	System.Windows.Forms.Keys.O
VbKeyP(80)	System.Windows.Forms.Keys.P
VbKeyQ (81)	System.Windows.Forms.Keys.Q
VbKeyR (82)	System.Windows.Forms.Keys.R
VbKeyS (83)	System.Windows.Forms.Keys.S
VbKeyT (84)	System.Windows.Forms.Keys.T
VbKeyU (85)	System.Windows.Forms.Keys.U
VbKeyV (86)	System.Windows.Forms.Keys.V
VbKeyW (87)	System.Windows.Forms.Keys.W
VbKeyX (88)	System.Windows.Forms.Keys.X
VbKeyY (89)	System.Windows.Forms.Keys.Y
VbKeyZ (90)	System.Windows.Forms.Keys.Z

Numeric Key Constants

Visual Basic 6.0	Visual Basic .NET Equivalent
vbKey0 (48)	System.Windows.Forms.Keys.D0
vbKey1 (49)	System.Windows.Forms.Keys.D1
vbKey2 (50)	System.Windows.Forms.Keys.D2
vbKey3 (51)	System.Windows.Forms.Keys.D3
vbKey4 (52)	System.Windows.Forms.Keys.D4
vbKey5 (53)	System.Windows.Forms.Keys.D5
vbKey6 (54)	System.Windows.Forms.Keys.D6
vbKey7 (55)	System.Windows.Forms.Keys.D7
vbKey8 (56)	System.Windows.Forms.Keys.D8
vbKey9 (57)	System.Windows.Forms.Keys.D9

Numeric Keypad Key Constants

Visual Basic 6.0	Visual Basic .NET Equivalent
vbKeyNumpad0 (96)	System.Windows.Forms.Keys.NumPad0
vbKeyNumpad1 (97)	System.Windows.Forms.Keys.NumPad1
vbKeyNumpad2 (98)	System.Windows.Forms.Keys.NumPad2
vbKeyNumpad3 (99)	System.Windows.Forms.Keys.NumPad3
vbKeyNumpad4 (100)	System.Windows.Forms.Keys.NumPad4
vbKeyNumpad5 (101)	System.Windows.Forms.Keys.NumPad5
vbKeyNumpad6 (102)	System.Windows.Forms.Keys.NumPad6
vbKeyNumpad7 (103)	System.Windows.Forms.Keys.NumPad7
vbKeyNumpad8 (104)	System.Windows.Forms.Keys.NumPad8
vbKeyNumpad9 (105)	System.Windows.Forms.Keys.NumPad9
VbKeyMultiply (106)	System.Windows.Forms.Keys.Multiply
VbKeyAdd (107)	System.Windows.Forms.Keys.Add
VbKeySeparator (108)	System.Windows.Forms.Keys.Separator
VbKeySubtract (109)	System.Windows.Forms.Keys.Subtract
VbKeyDecimal (110)	System.Windows.Forms.Keys.Decimal
VbKeyDivide (111)	System.Windows.Forms.Keys.Divide

Function Key Constants

Visual Basic 6.0	Visual Basic .NET Equivalent
vbKeyF1 (112)	System.Windows.Forms.Keys.F1
vbKeyF2 (113)	System.Windows.Forms.Keys.F2
vbKeyF3 (114)	System.Windows.Forms.Keys.F3
vbKeyF4 (115)	System.Windows.Forms.Keys.F4
vbKeyF5 (116)	System.Windows.Forms.Keys.F5
vbKeyF6 (117)	System.Windows.Forms.Keys.F6
vbKeyF7 (118)	System.Windows.Forms.Keys.F7

vbKeyF8 (119)	**System.Windows.Forms.Keys.F8**
vbKeyF9 (120)	**System.Windows.Forms.Keys.F9**
vbKeyF10 (121)	**System.Windows.Forms.Keys.F10**
vbKeyF11 (122)	**System.Windows.Forms.Keys.F11**
vbKeyF12 (123)	**System.Windows.Forms.Keys.F12**
vbKeyF13 (124)	**System.Windows.Forms.Keys.F13**
vbKeyF14 (125)	**System.Windows.Forms.Keys.F14**
vbKeyF15 (126)	**System.Windows.Forms.Keys.F15**
vbKeyF16 (127)	**System.Windows.Forms.Keys.F16**

Style Constant Changes in Visual Basic .NET

The following tables show the Visual Basic 6.0 **Style** constants and values and their Visual Basic .NET equivalents.

ComboBox Style Constants

Visual Basic 6.0	Visual Basic .NET Equivalent
vbComboDropdown (0)	System.Windows.Forms.ComboBoxStyle.DropDown
vbComboSimple (1)	System.Windows.Forms.ComboBoxStyle.Simple
vbComboDropdownList (2)	System.Windows.Forms.ComboBoxStyle.DropDownList

CheckBox and OptionButton Style Constants

Visual Basic 6.0	Visual Basic .NET Equivalent
VbButtonStandard (0)	System.Windows.Forms.Appearance.Normal
VbButtonGraphical (1)	System.Windows.Forms.Appearance.Button

> **Note** In Visual Basic 6.0, **Style** constants were also defined for **CommandButton** and **ListBox** controls. There are no equivalents in Visual Basic .NET. For details, see Style Property Changes in Visual Basic .NET or ListBox Control Changes in Visual Basic .NET.| Constants and Enumerations

System Color Constant Changes in Visual Basic .NET

The following table shows the Visual Basic 6.0 **System Color** constants and their Visual Basic .NET equivalents.

Visual Basic 6.0	Visual Basic .NET Equivalent
vb3DDKShadow	System.Drawing.SystemColors.ControlDarkDark
vb3DFace	System.Drawing.SystemColors.Control
vb3DHighlight	System.Drawing.SystemColors.ControlLightLight
vb3DLight	System.Drawing.SystemColors.ControlLight
vb3DShadow	System.Drawing.SystemColors.ControlDark
vbActiveBorder	System.Drawing.SystemColors.ActiveBorder
vbActiveTitleBar	System.Drawing.SystemColors.ActiveCaption
vbActiveTitleBarText	System.Drawing.SystemColors.ActiveCaptionText
vbApplicationWorkspace	System.Drawing.SystemColors.AppWorkspace
vbButtonFace	System.Drawing.SystemColors.Control
vbButtonShadow	System.Drawing.SystemColors.ControlDark
vbButtonText	System.Drawing.SystemColors.ControlText
vbDesktop	System.Drawing.SystemColors.Desktop
vbGrayText	System.Drawing.SystemColors.GrayText
vbHighlight	System.Drawing.SystemColors.Highlight
vbHighlightText	System.Drawing.SystemColors.HighlightText
vbInactiveBorder	System.Drawing.SystemColors.InactiveBorder
vbInactiveCaptionText	System.Drawing.SystemColors.InactiveCaptionText
vbInactiveTitleBar	System.Drawing.SystemColors.InactiveCaption
vbInactiveTitleBarText	System.Drawing.SystemColors.InactiveCaptionText
vbInfoBackground	System.Drawing.SystemColors.Info
vbInfoText	System.Drawing.SystemColors.InfoText
vbMenuBar	System.Drawing.SystemColors.Menu
vbMenuText	System.Drawing.SystemColors.MenuText
vbScrollBars	System.Drawing.SystemColors.Scrollbar
vbTitleBarText	System.Drawing.SystemColors.ActiveCaptionText
vbWindowBackground	System.Drawing.SystemColors.Window
vbWindowFrame	System.Drawing.SystemColors.WindowFrame
vbWindowText	System.Drawing.SystemColors.WindowText

Namespace Changes in Visual Basic .NET

Namespaces may at first seem to be a new concept in Visual Basic .NET; conceptually they are similar to object libraries in Visual Basic 6.0.

In Visual Basic 6.0, various libraries contained objects that were used to build an application. For example, the Visual Basic library contained the form object and intrinsic control objects that were the foundation of a Windows application. You could see the objects contained in a given library by viewing it in the Object Browser.

In Visual Basic .NET, objects are contained in assemblies that are part of the .NET Framework Class Library. Each assembly represents a namespace. For example, form and control objects are contained in the **System.Windows.Forms** namespace. As in Visual Basic 6.0, namespaces can be inspected in the Object Browser.

Introduction to the .NET Framework Class Library in Visual Studio

Run-Time Changes in Visual Basic .NET

For applications created with Visual Basic 6.0, the Visual Basic run-time file (Msvbvm60.dll) had to be installed on a client computer in order for the application to run. This file was often included in Setup packages so that it could be installed along with the application if necessary.

In Visual Basic .NET, applications require the .NET Framework common language runtime, a run-time environment that manages the execution of code on a client computer. The common language runtime files are packaged in a merge module that is automatically included in installers built using Visual Studio deployment projects.

Upgrading Applications Created in Previous Versions of Visual Basic

Visual Studio .NET provides the ability to upgrade applications created in Visual Basic 6.0 so that you can continue development, taking advantage of the benefits of the .NET Platform. When you first open a Visual Basic 6.0 project file (.vbp), the Upgrade Wizard will appear. A command-line tool is also provided for upgrading projects outside of the Visual Studio environment.

The upgrading tools modify the code within your project to comply with Visual Basic .NET syntax and replace any forms and controls with Visual Basic .NET equivalents. Due to the differences between Visual Basic 6.0 and Visual Basic. NET, some things in your project may not map directly — in these cases, an upgrade report is provided to guide you through the process of modifying your application.

Some Visual Basic 6.0 applications may not benefit from being upgraded to Visual Basic .NET. In addition, there are some things that you can do to your Visual Basic 6.0 applications that will help to make the upgrade process go smoothly.

The following topics will help you better understand the upgrade process.

Why Upgrading Is Necessary

There were two options to consider when designing Visual Basic .NET — retrofit the existing code base to run on top of the .NET Framework, or build from the ground up, taking full advantage of the platform. To deliver the features most requested by customers (for example, inheritance, threading), to provide full and unconstrained access to the platform, and to ensure that Visual Basic moves forward into the next generation of Web applications, the right decision was to build from the ground up on the new platform.

For example, many of the new features found in Windows Forms (the new forms package) could have been added to the existing code base as new controls or more properties. However, this would have been at the cost of all the other great features inherent to Windows Application Objects, such as security and visual inheritance.

One of the major goals for Visual Basic was to ensure that code could fully interoperate with code written in other languages, such as C# or C++, and enable the Visual Basic developer to harness the power of the .NET Framework simply, without resorting to the programming workarounds traditionally required to make Windows APIs work. Visual Basic now has the same variable types, arrays, user-defined types, classes, and interfaces as Visual C++ and any other language that targets the common language runtime; however, some features such as fixed-length strings had to be removed from the language.

Visual Basic is now a true object-oriented language; some unintuitive and inconsistent features like GoSub/Return and DefInt have been removed from the language.

The result is a re-energized Visual Basic, which will continue to be the most productive tool for creating Windows-based applications and is now positioned to be the best tool for creating the next-generation Web sites. The tradeoff is that Visual Basic 6.0 applications must be upgraded to conform to the new language and forms features, breaking compatibility with earlier versions.

Upgrading Applications Created in Previous Versions of Visual Basic

Things to Consider Before Upgrading

Visual Basic .NET represents a major shift from previous versions of Visual Basic. Because it was designed from the ground up to take advantage of the .NET Platform, there are many areas where compatibility with previous versions is broken.

> **Note** Visual Basic .NET and Visual Basic 6.0 can be installed on the same computer and run at the same time. Applications written in Visual Basic .NET and Visual Basic 6.0 can be installed and executed on the same computer. Components written in Visual Basic .NET can interoperate with COM components written in earlier versions of Visual Basic and other languages.

In most cases you will want to upgrade your Visual Basic 6.0 applications to Visual Basic .NET so that you can take advantage of the benefits of the .NET Platform as you continue development. There are, however, situations where you may wish to continue development in Visual Basic 6.0 rather than upgrading. Some of the factors in deciding to upgrade an application include features that aren't supported in Visual Basic .NET, and the amount of rework needed due to incompatibility and architectural considerations.

- Unsupported Features
- Determining the Amount of Rework Required

Unsupported Features

The following features from Visual Basic 6.0 are no longer supported in Visual Basic .NET. For more information, see Preparing a Visual Basic 6.0 Application for Upgrading.

- **OLE Container Control** There is no equivalent in Visual Basic .NET. Applications that depend on this control should be left in Visual Basic 6.0.
- **Dynamic Data Exchange (DDE)** DDE methods are no longer supported. Applications that depend on DDE should either be revised to use another method of inter-application communication or should be left in Visual Basic 6.0.
- **DAO or RDO Data Binding** Data binding to a DAO or RDO data source isn't supported in Visual Basic .NET; the **Data** control and the **RemoteData** control have no equivalent. DAO and RDO can only be accessed via code. Applications that rely on DAO or RDO data binding should either be updated to use ADO or should be left in Visual Basic 6.0.
- **Visual Basic 5.0 Controls** Visual Basic 6.0 included the Visual Basic 5.0 versions of the Windows Common controls and the **Data-Bound Grid** control. These controls are incompatible with Visual Basic .NET. Applications that rely on these controls should either be updated to use the 6.0 versions or should be left in Visual Basic 6.0.
- **DHTML Applications** There is no equivalent in Visual Basic .NET. However, DHTML applications can interoperate with Visual Basic .NET technologies.
- **ActiveX Documents** There is no equivalent in Visual Basic .NET. However, DHTML applications can interoperate with Visual Basic .NET technologies. ActiveX documents should either be rewritten as User Controls, or left in Visual Basic 6.0.
- **Property Pages** There is no equivalent in Visual Basic .NET. If your application depends heavily on property pages, it should be left in Visual Basic 6.0.

Determining the Amount of Rework Required

Due to the many differences between Visual Basic 6.0 and Visual Basic .NET, most applications will require some rework for items that can't be mapped directly or are otherwise incompatible. The amount of rework required depends on a number of factors, including the type of application, features, and the language constructs used.

The easiest way to determine the amount of rework required is to run the Upgrade Wizard and view the list of issues in the Upgrade Report. When an application is upgraded a new copy is created; the original application is left intact. If, after viewing the report, you decide not to upgrade, you can simply delete the new project and continue development in Visual Basic 6.0.

The following are additional considerations that may factor into your upgrade decision.

- **Single-tier Database Applications** Because data binding to DAO isn't supported, simple applications using controls bound directly to a local database (such as one created with Microsoft Access) may require a significant amount of rework.
- **Visual Basic Add-ins** Because Visual Basic .NET uses the Visual Studio integrated development environment, the object model for extensibility is significantly different than that of Visual Basic 6.0. Add-ins will require a considerable amount of rework.
- **Games** Applications relying on specific performance characteristics of Visual Basic 6.0, such as arcade games, will require rework because Visual Basic .NET has different performance characteristics.

- **Graphics** There is no support for the graphics methods of forms or for the shape and line controls. Applications that use these features extensively to draw on forms will require considerable rework.
- **Drag and Drop Functionality** The models for drag and drop functionality are significantly different; any code performing drag and drop actions will need to be rewritten.
- **Variants** When an application is upgraded, the **Variant** data type is converted to **Object**. If an application is heavily dependent on variants, this conversion can introduce some subtle differences in the application's behavior. For example, in Visual Basic 6.0 the expression `IsObject(Variant)` evaluates to **false**; in Visual Basic .NET it changes to `IsObject(Object)`, which evaluates to **true**.
- **Windows APIs** Due to language changes, many calls to Windows APIs will need to be revised or replaced with .NET Framework functions.

Upgrading Applications Created in Previous Versions of Visual Basic

Preparing a Visual Basic 6.0 Application for Upgrading

Although the process of upgrading a Visual Basic 6.0 application to Visual Basic .NET is for the most part automatic, there are a number of things you can do to optimize your upgrade with a little bit of preparation.

By following the recommendations in this topic, you can minimize and, in some cases, eliminate the changes needed after upgrading your project to Visual Basic .NET. In most cases, the recommendations simply represent good programming practices; however, some also identify the objects and methods which have no equivalents, and which should be used sparingly if you intend to upgrade your project to Visual Basic .NET.

- General Recommendations
- Considerations for Forms and Controls
- Data Recommendations
- Web Architecture Recommendations

General Recommendations

This may seem obvious, but if your project doesn't compile and run under Visual Basic 6.0, it will not be upgraded successfully. It is recommended that you install Visual Basic 6.0 on the computer that you will be using for upgrading. In addition to allowing you to test the application, this will ensure that all necessary controls, components, and type libraries are available during upgrade.

Visual Basic .NET allows you to upgrade Visual Basic 6.0 projects; if you have a project written in Visual Basic version 1 to 5, you should first load it into Visual Basic 6.0 (choosing to upgrade Microsoft ActiveX controls), compile, and save the project before upgrading it to Visual Basic .NET.

Considerations for Forms and Controls

Visual Basic .NET has a new forms package, Windows Forms. Windows Forms is largely compatible with the forms package found in Visual Basic 6.0; however, there are some key differences that are outlined below:

- Visual Basic .NET does not support the OLE container control; you should avoid using this control in your Visual Basic 6.0 applications.
- There is no shape control in Visual Basic .NET. Square and rectangular shapes will be upgraded to labels, while ovals and circles cannot be upgraded. You should avoid using these in your applications.
- There is no line control in Visual Basic .NET. Horizontal and vertical lines are upgraded to labels. Diagonal lines are not upgraded, and you should avoid using them.
- Visual Basic .NET has a new set of graphics commands that replace the Form methods **Circle**, **CLS**, **PSet**, **Line**, and **Point**. Because the new object model is quite different from Visual Basic 6.0, these methods cannot be upgraded.
- For the Timer control, setting the **Interval** property to 0 does not disable the timer; instead the interval is reset to 1. In your Visual Basic 6.0 projects, you should set **Enabled** to **False** instead of setting the **Interval** to 0.

Visual Basic .NET has two menu controls, **MainMenu** and **ContextMenu**, whereas Visual Basic 6.0 has one menu control that can be opened as either a **MainMenu** or a **ContextMenu** controls. All menu controls are upgraded to a single **MainMenu** component containing **MenuItems** for each menu control; you will have to recreate your **ContextMenus** and delete the extra **MainMenu** controls.

- Visual Basic .NET has no support for Dynamic Data Exchange (DDE).
- Visual Basic .NET does not support the **Form.PrintForm** method.
- Although Visual Basic .NET has support for drag-and-drop functionality, the object model is different from the one in Visual Basic 6.0. Therefore, the Visual Basic 6.0 drag-and-drop properties and methods cannot be upgraded.
- The .NET Framework has an improved **Clipboard** object (**System.Windows.Forms.Clipboard**) that offers more functionality and supports more clipboard formats than the Visual Basic 6.0 **Clipboard** object. However, because of differences between object models, clipboard statements cannot be automatically upgraded.
- Visual Basic .NET does not support the **Name** property for forms and controls at run time; therefore you should not write code that iterates the **Controls** collection looking for a control with a certain name (this functionality is now available using the .NET **System.Reflection** classes.)

Data Recommendations

Visual Basic .NET introduces an enhanced version of ADO called ADO.NET that is optimized to work with data in distributed

applications and that provides performance improvements over ADO when used in distributed applications.

DAO, RDO, and ADO can still be used in code from Visual Basic .NET, with some trivial modifications (covered in the language section of this document). However, Visual Basic .NET does not support DAO and RDO data binding to controls, data controls, or RDO User connection. We recommend that if your applications contain DAO or RDO data binding you either leave them in Visual Basic 6.0 or upgrade the DAO or RDO data binding to ADO before upgrading your project to Visual Basic .NET, as ADO data binding is supported in Windows Forms. Information on how to upgrade DAO or RDO to ADO in Visual Basic 6.0 is available in the Visual Basic 6.0 Help.

Web Architecture Recommendations

Visual Basic .NET introduces ASP.NET, an enhanced version of ASP, and adds to the architecture with Web Forms, a technology for producing Web pages with a Visual Basic-like event model. The architecture is server-based.

For Web-based applications, applications that conform to the Microsoft multitier architecture guidelines, use Active Server Pages (ASP), and use Visual Basic 6.0 or Visual C++ 6.0 COM objects for business logic will be the easiest to upgrade. ASP is fully supported in Visual Basic .NET, and you can continue to extend your application using ASP, ASP.NET, and Web Forms. The Visual Basic 6.0 and Visual C++ 6.0 business objects can either be used without modification or upgraded to Visual Studio .NET.

Webclasses no longer exist in Visual Basic .NET. Existing Webclass applications can interoperate with Visual Basic .NET Web Forms and ASP applications; or they can be upgraded to Web Forms applications.

Language Recommendations for Upgrading

Differences in language between Visual Basic 6.0 and Visual Basic .NET necessitate changes to code when an application is upgraded. The following are some recommendations you can follow when preparing a Visual Basic 6.0 application for upgrade, or when developing Visual Basic 6.0 applications that might later be upgraded.

In This Section

Upgrade Recommendation: Use Early Binding and Explicit Conversions

Upgrade Recommendation: Use the Date Data Type for Storing Dates

Upgrade Recommendation: Resolve Parameterless Default Properties

Upgrade Recommendation: Avoid Null Propagation

Upgrade Recommendation: Use Zero-Bound Arrays

Upgrade Recommendation: Use Constants Instead of Underlying Values

Upgrade Recommendation: Avoid Arrays and Fixed-Length Strings in User-Defined Types

Upgrade Recommendation: Avoid Legacy Keywords

Upgrade Recommendation: Adjust Data Types for Win32 APIs

Things to Consider Before Upgrading
Discusses the limitations of and considerations for upgrading.

Upgrading Applications Created in Previous Versions of Visual Basic
Discusses upgrading your Visual Basic 6.0 applications.

Upgrade Recommendation: Use Early Binding and Explicit Conversions

Both Visual Basic 6.0 and Visual Basic .NET support late-bound objects, which is the practice of declaring a variable as the **Object** data type and assigning it to an instance of a class at run time. However, during the upgrade process, late-bound objects can introduce problems when resolving default properties, or in cases where the underlying object model has changed and properties, methods, and events need to be converted. For example, suppose you have a form called Form1 with a label called Label1; the following Visual Basic 6.0 code would set the caption of the label to "SomeText":

```
Dim o As Object
Set o = Me.Label1
o.Caption = "SomeText"
```

In Visual Basic .NET, the **Caption** property of a label control is replaced by the **Text** property. When your code is upgraded, all instances of the **Caption** property are changed to **Text**, but because a late-bound object is type-less, Visual Basic cannot detect what type of object it is, or if any properties should be translated. In such cases, you will need to change the code yourself after upgrading.

If you rewrite the code using early-bound objects, it will be upgraded automatically:

```
Dim o As Label
Set o = Me.Label1
o.Text = "SomeText"
```

Where possible you should declare variables of the appropriate object type rather than simply declaring them as the **Object** data type.

In the cases where you do use Object and Variant variables in your Visual Basic 6.0 code, we recommend you use explicit conversions when you assign the variables, perform operations on the variables, or pass the variables to a function. For example, the intention of the '+' operation in the following code is unclear:

```
Dim Var1 As Variant
Dim Var2 As Variant
Dim Var3 As Variant
Var1 = "3"
Var2 = 4
'BAD: Should Var1 and Var2 be added as strings or integers?
Var3 = Var1 + Var2
```

The above example may result in a run-time error in Visual Basic .NET. Rewriting the final line to use explicit conversions ensures the code will work:

```
'GOOD: explicit conversion
Var3 = CInt(Var1) + CInt(Var2)
```

Visual Basic .NET supports overloading functions based on parameter type. For example, the **Environ** function now has two forms:

```
Environ( Expression As Integer) As String
Environ( Expression As String ) As String
```

Visual Basic .NET determines which function to call based on the parameter type. If you pass an integer to **Environ()**, the integer version is called; if you pass a string, then the string version is called. Code that passes a **Variant** or **Object** data type to an overloaded function may cause a compile or run-time error. Using an explicit conversion, as in the following example, will mean your code will work as intended after it is upgraded to Visual Basic .NET:

```
Dim a As String
Dim v As Variant
v = "Path"
```

```
'GOOD: explicit conversion
a = Environ(CStr(v))
```

Using explicit conversions of late-bound objects is good coding practice. It makes the intention of the code easy to determine, and makes it easier for you to upgrade your project to Visual Basic .NET.

See Also

Language Recommendations for Upgrading

Upgrade Recommendation: Use the Date Data Type for Storing Dates

Earlier versions of Visual Basic supported using the **Double** data type to store and manipulate dates. You should not do this in Visual Basic .NET, because dates are not internally stored as doubles. For example, the following is valid in Visual Basic 6.0, but may cause a compile error in Visual Basic .NET:

```
Dim dbl As Double
Dim dat As Date
dat = Now
'BAD: Date can't be assigned to a double
dbl = dat
'BAD: Double can't be used in date functions
dbl = DateAdd("d", 1, dbl)
'BAD: CDate can't convert a double to a date
dat = CDate(dbl)
```

The .NET Framework provides the **ToOADate** and **FromOADate** functions to convert between doubles and dates. However, when your project is upgraded to Visual Basic .NET, it is difficult to determine the intention of code that uses doubles to store dates. To avoid unnecessary modifications to your code in Visual Basic .NET, always use the **Date** data type to store dates.

See Also

Language Recommendations for Upgrading

Upgrade Recommendation: Resolve Parameterless Default Properties

In Visual Basic 6.0, many objects expose default properties, which can be omitted as a programming shortcut. For example, **TextBox** has a default property of **Text**, so instead of writing:

```
MsgBox Form1.Text1.Text
```

you use the shortcut:

```
MsgBox Form1.Text1
```

The default property is resolved when the code is compiled. In addition, you could also use default properties with late-bound objects, as in the following example:

```
Dim obj As Object
Set obj = Form1.Text1
MsgBox obj
```

In the late-bound example, the default property is resolved at run time, and the **MsgBox** displays the value of the default property of the **TextBox** as **Text1**.

Visual Basic .NET does not support parameterless default properties, and consequently does not allow this programming shortcut. When your project is upgraded, Visual Basic .NET resolves the parameterless default properties, but late-bound usages that rely on run-time resolution cannot be automatically resolved. In these cases, you will have to change the code yourself. An additional complication is that many libraries implement default properties using a property called **_Default**. **_Default** acts as a proxy, passing calls to the real default property. So, when your project is upgraded, some default properties will be resolved to **_Default**. The code will still work as usual, but it will be less understandable than code written explicitly using the actual property. For these reasons, try to avoid using parameterless default properties in your Visual Basic 6.0 code. Instead of writing:

```
Dim obj As Object
Set obj = Me.Text1
'BAD: Relying on default property
MsgBox obj
'BAD: Relying on default property
MsgBox Me.Text1
```

use:

```
Dim obj As TextBox
Set obj = Me.Text1
'GOOD: Default property is resolved
MsgBox obj.Text
'GOOD: Default property is resolved
MsgBox Me.Text1.Text
```

While *parameterless* default properties are not supported in Visual Basic .NET, default properties *with parameters* are supported. To understand the difference between the two types, consider that parameterized default properties always have an index. An example is the default property of ADO **recordset**: the **Fields** collection. The code:

```
Dim rs As ADODB.Recordset
rs("CompanyName") = "SomeCompany"
rs!CompanyName = "SomeCompany"
```

is actually a shortcut for:

```
Dim rs As ADODB.Recordset
rs.Fields("CompanyName").Value = "SomeCompany"
```

```
rs.Fields!CompanyName.Value = "SomeCompany"
```

In this case, the **Fields** property is parameterized, and so the usage is valid in Visual Basic .NET; however, the default property of the **Fields** property, **Value,** is parameterless, so the correct usage in Visual Basic .NET is:

```
Dim rs As ADODB.Recordset
rs("CompanyName").Value = "SomeCompany"
rs!CompanyName.Value = "SomeCompany"
```

This example and most other default properties are resolved for you when the project is upgraded, so resolving them in Visual Basic 6.0 is simply a good programming practice. However, you should avoid using default properties with the **Object** and **Variant** data types, as these cannot be resolved and you will have to fix the code yourself in the upgraded project.

Language Recommendations for Upgrading

Upgrade Recommendation: Avoid Null Propagation

Previous versions of Visual Basic supported Null propagation. Null propagation supports the premise that when Null is used in an expression, the result of the expression will itself be Null. In each case in the following example, the result of `V` is always Null.

```
Dim V
V = 1 + Null
V = Null + Right$("SomeText", 1)
V = Right("SomeText", 0)
```

Null propagation is not supported in Visual Basic .NET. The statement `1+Null` will generate a type mismatch in Visual Basic .NET. Additionally, where Visual Basic 6.0 had two versions of the Left function — **Left$** returning a string, **Left** returning a variant which could be Null — Visual Basic .NET only has one version, **Left**, which always returns a string.

In order to be compatible with both Visual Basic 6.0 and Visual Basic .NET, you should always write code to test for Null instead of relying on Null propagation. Furthermore, in Visual Basic .NET, the following functions will no longer return Null:

Chr, **Command**, **CurDir**, **Date**, **Environ**, **Error**, **Hex**, **LCase**, **LTrim**, **Oct**, **Right**, **RTrim**, **Space**, **Str**, **Time**, **Trim**, **UCase**.

Null propagation is commonly used in database applications, where you need to check if a database field contains Null. In these cases you should check results using the function **IsNull()** and perform the appropriate action.

Language Recommendations for Upgrading

Upgrade Recommendation: Use Zero-Bound Arrays

Visual Basic 6.0 allowed you to define arrays with lower and upper bounds of any whole number. You could also use **ReDim** to reassign a variant as an array. To enable interoperability with other languages, arrays in Visual Basic .NET must have a lower bound of zero, and **ReDim** cannot be used unless the array variable was previously declared with the **Dim** keyword. Although this restricts the way arrays can be defined, it does allow you to pass arrays between Visual Basic .NET and any other .NET language. The following example shows the restriction:

```
'BAD: LBound must be 0
Dim a(1 To 10) As Integer
'BAD: Can't use ReDim without Dim
ReDim v(10)
'OK: Creates an array of 11 integers
Dim b(10) As Integer
'OK: Can ReDim previously Dimed variable
ReDim b(5) As Integer
```

A side effect is that the **Option Base** statement is removed from the language.

When your project is upgraded to Visual Basic .NET, any option base statements are removed from your code. If the array is zero-bound, it is left unchanged. However, if an array is non-zero–bound, then the lower bound is removed and a warning is inserted into the code, as in the following example:

```
Dim a(1 To 10) As Integer
```

changes to:

```
' UPGRADE_WARNING: Lower bound of an array was changed from 1 to 0.
Dim a(10) As Integer
```

In many cases, the upgraded code will work as it did before. However, if your application logic relies on the lower bound being 1, then you will need to make some modifications. **Dim**, **ReDim**, and **LBound** statements are marked with warnings to help you review the changes.

For this reason, you should use zero-bound arrays in your Visual Basic 6.0 code, avoid using **ReDim** as an array declaration, and avoid using **Option Base** 1.

Language Recommendations for Upgrading

Upgrade Recommendation: Use Constants Instead of Underlying Values

When writing code, try to use constants rather than relying on their underlying values. For example, if you are maximizing a form at run time, use:

```
' GOOD: Constant name
Me.WindowState = vbMaximized
```

rather than:

```
'BAD: Underlying value
Me.WindowStyle = 2
'BAD: Variable
Me.WindowStyle = X
```

Likewise, use **True** and **False** instead of -1 and 0.

In Visual Basic .NET, the values and in some cases the names of some properties and constants have changed; for example, the value of **True** changes from -1 to 1. When your project is upgraded to Visual Basic .NET, most constants are changed automatically for you; however, if you use underlying values or variables instead of the constant names, many cases cannot be upgraded automatically. Using constant names minimizes the number of modifications you have to do.

Language Recommendations for Upgrading

Upgrade Recommendation: Avoid Arrays and Fixed-Length Strings in User-Defined Types

Due to changes made which allow Visual Basic .NET arrays and structures (formerly known as user-defined types) to be fully compatible with other Visual Studio .NET languages, fixed-length strings are no longer supported in the language. In most cases this is not a problem, because there is a compatibility class which provides fixed-length string behavior, so the code:

```
Dim MyFixedLengthString As String * 100
```

upgrades to the following:

```
Dim MyFixedLengthString As New VB6.FixedLengthString(100)
```

However, fixed-length strings do cause a problem when used in structures. The problem arises because the fixed-length string class is not automatically created when the structure is created. Likewise, fixed-size arrays are not created when the structure is created.

When your code is upgraded, user-defined types with fixed-length strings or arrays will be converted to structures and marked with a comment telling you to initialize the fixed-length string or array before referencing the structure in code. However, you can shield yourself from this modification by changing your Visual Basic 6.0 user-defined types to use strings instead of fixed-length strings, and uninitialized arrays instead of fixed-size arrays. For example:

```
Private Type MyType
    MyArray(5) As Integer
    MyFixedString As String * 100
End Type
Sub Bar()
    Dim MyVariable As MyType
End Sub
```

can be changed to:

```
Private Type MyType
    MyArray() As Integer
    MyFixedString As String
End Type
Sub Bar()
    Dim MyVariable As MyType
    ReDim MyVariable.MyArray(5) As Integer
    MyVariable.MyFixedString = String$(100, " ")
End Sub
```

See Also

Language Recommendations for Upgrading

Upgrade Recommendation: Avoid Legacy Keywords

Because they have been removed from the language, you should avoid using the following keywords.

Keyword	Explanation
Def<*type*>	In previous versions of Visual Basic, **DefBool**, **DefByte**, **DefInt**, **DefLng**, **DefCur**, **DefSng**, **DefDbl**, **DefDec**, **DefDate**, **DefStr**, **DefObj** and **DefVar** were used in the declarations section of a module to define a range of variables as a certain type. For example `DefInt A-C` defined all variables beginning with the letter A, B, or C as an integer. Instead of using **Def**<type> statements, you should explicitly declare variables.
Computed **GoTo/GoSub**	Computed **GoTo**/**GoSub** statements take this form: `On x GoTo 100, 200, 300` These are not supported in Visual Basic .NET. Instead, you should use **If** statements, or **Select Case** constructs.
GoSub/Return	**GoSub** and **Return** statements are not supported in Visual Basic .NET. In most cases you can replace these with functions and procedures.
Option Base 0|1	The **Option Base** statement was used to specify the default lower bound of an array as either 0 or 1. This statement has been removed from the language since Visual Basic .NET natively only supports arrays with a zero lower bound. Non-zero lower bound arrays are supported through the VB6.Compatibility class.
VarPtr, **ObjPtr**, **StrPtr**	**VarPtr**, **VarPtrArray**, **VarPtrStringArray**, **ObjPtr** and **StrPtr** were undocumented functions used to get the underlying memory address of variables. These functions are not supported in Visual Basic .NET.
LSet	In Visual Basic 6.0, the **LSet** statement could be used to assign a variable of one user-defined type to another variable of a different user-defined type. This functionality is not supported in Visual Basic .NET.

Language Recommendations for Upgrading

Upgrade Recommendation: Adjust Data Types for Win32 APIs

Many APIs can be used exactly as they were in Visual Basic 6.0, with the caveat that you have to adjust your data types accordingly. The Visual Basic 6.0 **Long** data type is now the Visual Basic .NET **Integer** data type, and the Visual Basic 6.0 **Integer** data type is now the Visual Basic .NET **Short** data type. During the upgrade, these changes are made for you, and simple APIs work exactly the same as they did in Visual Basic 6.0. For example:

```
Private Declare Function GetVersion Lib "kernel32" () As Long
Function GetVer()
    Dim Ver As Long
    Ver = GetVersion()
    MsgBox ("System Version is " & Ver)
End Function
```

changes to:

```
Private Declare Function GetVersion Lib "kernel32" () As Integer
Function GetVer()
    Dim Ver As Integer
    Ver = GetVersion()
    MsgBox("System Version is " & Ver)
End Function
```

In addition to numeric data type upgrades, Visual Basic 6.0 had a fixed-length string data type which is not supported in Visual Basic .NET, and which is upgraded to a fixed-length string wrapper class. In many cases in Visual Basic 6.0 you can perform the same action using a normal string. For example:

```
Private Declare Function GetUserName Lib "advapi32.dll" Alias _
"GetUserNameA" (ByVal lpBuffer As String, ByRef nSize As Long) As Long
Function GetUser()
    Dim Ret As Long
    Dim UserName As String
    Dim Buffer As String * 25
    Ret = GetUserName(Buffer, 25)
    UserName = Left$(Buffer, InStr(Buffer, Chr(0)) - 1)
    MsgBox (UserName)
End Function
```

can be better written using a normal string explicitly set to length 25 instead of a fixed-length string:

```
Dim Buffer As String
Buffer = String$(25, " ")
```

This is upgraded to Visual Basic .NET as follows:

```
Declare Function GetUserName Lib "advapi32.dll" Alias _
"GetUserNameA" (ByVal lpBuffer As String, ByRef nSize As Integer) As Integer
Function GetUser()
    Dim Ret As Integer
    Dim UserName As String
    Dim Buffer As String
    Buffer = New String(CChar(" "), 25)
    Ret = GetUserName(Buffer, 25)
    UserName = Left(Buffer, InStr(Buffer, Chr(0)) - 1)
    MsgBox(UserName)
End Function
```

In some cases, Visual Basic .NET better handles passing strings to APIs, since you can optionally declare how you want strings to be passed using the **ANSI** and **UNICODE** keywords.

There are three cases where you may need to make some changes. The first is passing user-defined types that contain fixed-

length strings or byte arrays to APIs. In Visual Basic .NET you may need to change your code, adding the **MarshallAs** attribute (from **System.Runtime.InteropServices**) to each fixed-length string or byte array in the user-defined type. The second case is using the **As Any** variable type in a **Declare** statement. This is not supported in Visual Basic .NET. Variables of type **As Any** were often used to pass a variable that was either a string or Null; you can replace this Visual Basic 6.0 usage by declaring two forms of the API, one with longs, one with strings. For example, the GetPrivateProfileString API has a parameter lpKeyName of type **As Any**:

```
Private Declare Function GetPrivateProfileString Lib "kernel32" Alias _
"GetPrivateProfileStringA" (ByVal lpApplicationName As String, ByVal _
lpKeyName As Any, ByVal lpDefault As String, ByVal lpReturnedString _
As String, ByVal nSize As Long, ByVal lpFileName As String) As Long
```

You can remove the "**As Any**" by replacing the **Declare** with two versions, one that accepts a long, and one that accepts a string:

```
Private Declare Function GetPrivateProfileStringKey Lib "kernel32" Alias _
"GetPrivateProfileStringA" (ByVal lpApplicationName As String, ByVal _
lpKeyName As String, ByVal lpDefault As String, ByVal lpReturnedString _
As String, ByVal nSize As Long, ByVal lpFileName As String) As Long

Private Declare Function GetPrivateProfileStringNullKey Lib "kernel32" _
Alias "GetPrivateProfileStringA" (ByVal lpApplicationName As String, _
ByVal lpKeyName As Long, ByVal lpDefault As String, ByVal _
lpReturnedString As String, ByVal nSize As Long, ByVal lpFileName _
As String) As Long
```

When you wish to pass the value Null to the API, you use the GetPrivateProfileStringNullKey version. Doing it this way means that the function upgrades to Visual Basic .NET.

The final area where you may need to make some changes is if you are using APIs that perform thread creation, Windows subclassing, message queue hooking, and so on. Some of these functions will cause a run-time error in Visual Basic .NET. Many of these APIs have equivalents in Visual Basic .NET or the .NET Framework. You will have to fix these on a case-by-case basis.

Language Recommendations for Upgrading

Visual Basic 6.0 Compatibility Library

If you have used previous versions of Visual Basic, you will notice that Visual Basic .NET introduces several changes to the Visual Basic language and that some familiar functions have seemingly disappeared. These changes were necessary in order to make Visual Basic compliant with the .NET Platform and the common language specification (CLS).

When a Visual Basic 6.0 application is upgraded to Visual Basic .NET, the conversion of some code is impossible due to syntactical or architectural differences. For this reason, functions in the Visual Basic 6.0 Compatibility library (Microsoft.VisualBasic.Compatibility) are used to allow the code to run in Visual Basic .NET without the need for extensive modification. These functions mimic Visual Basic 6.0 behavior while remaining compliant with the common language specification.

> **Caution** Functions in the Visual Basic 6.0 Compatibility library are provided only for use by the upgrading tools. Although it is possible to use this library when writing new code, there is no guarantee that it will be supported in future versions of Visual Basic.

Language Changes in Visual Basic | Working with Both Visual Basic 6.0 and Visual Basic .NET | Upgrading from Visual Basic 6.0

Visual Basic Upgrade Wizard

Visual Basic .NET enables a fundamental shift from traditional Windows development to building next-generation Web and n-tier applications. For this reason, your code will need to be upgraded to take advantage of Visual Basic .NET.

This happens automatically when you open a Visual Basic 6.0 project in Visual Basic .NET: the Upgrade Wizard steps you through the upgrade process and creates a new Visual Basic .NET project (your existing project is left unchanged). This is a one-way process; the new Visual Basic .NET project cannot be opened in Visual Basic 6.0.

When your project is upgraded, the language is modified for any syntax changes and your Visual Basic 6.0 Forms are converted to Windows Forms. In most cases, you will have to make some changes to your code after it is upgraded. This is required because certain objects and language features either have no equivalent in Visual Basic .NET, or have an equivalent too dissimilar for an automatic upgrade. After the upgrade, you may also want to change your application to take advantage of some of the new features in Visual Basic .NET.

To help you make the changes, after your project is upgraded, Visual Basic .NET adds an upgrade report to your project itemizing any problems, and inserts comments into your upgraded code alerting you to statements that will need to be changed. Because these comments are displayed as 'TO DO' tasks in the new Task List window, you can easily see what changes are required, and navigate to the code statement simply by double-clicking the task. Each task and item in the upgrade report is associated with an online Help topic giving further guidance as to why the code needs to be changed, and what you need to do

Completing the Upgrading Process | Why Upgrading is Necessary | Preparing a Visual Basic 6.0 Application for Upgrading | Upgrading Applications Created in Previous Versions of Visual Basic

Upgrading a Project with the Upgrade Wizard

The Visual Basic Upgrade Wizard can be used to upgrade Visual Basic 6.0 projects for further development in Visual Basic .NET. The Upgrade Wizard does not modify your original Visual Basic 6.0 project, but rather creates a new Visual Basic .NET project based on the original project.

> **Note** Although the wizard makes the upgrade process easier, you may be required to modify some code in the upgraded application. You should take some time to familiarize yourself with Visual Basic .NET before attempting this process.

To upgrade a Visual Basic 6.0 project to Visual Basic .NET

1. Open your project in Visual Basic 6.0. On the **File** menu, choose **Make *projectname***. Run the application and make sure that there are no errors.
2. Start Visual Studio .NET. On the **File** menu, choose **Open**, **Project**.
3. In the **Open Project** dialog box, browse to the location of the Visual Basic 6.0 project and select the project (.vbp) file.

   This will launch the Visual Basic Upgrade Wizard.

4. On the second page of the wizard, choose from the available upgrade options. The options will vary depending on the type of project being upgraded.

   > **Tip** For an explanation of available options, press **F1** while in the wizard.

5. On the third page of the wizard, enter the location where the new project will be created.

   > **Note** Each Visual Basic .NET project must be in its own folder. If you specify a folder that contains files, you will be prompted to choose a different folder.

6. On the fourth page of the wizard, click **Next** to begin the upgrade process. When the process is complete, the new project will appear in Solution Explorer.
7. In Solution Explorer, double-click the **_UpgradeReport.htm** node to open the upgrade report.
8. Review the upgrade report. Any errors must be fixed before you can run the application. Any warnings should be examined to make sure that they do not affect application behavior.

   > **Tip** For an explanation of any error or warning, click on the description to display a Help topic.

9. On the **Debug** menu, choose **Start.** Run the application and make sure that there are no errors and that the behavior is the same as it was in Visual Basic 6.0.

   > **Note** The Upgrade Wizard cannot catch all possible incompatibilities; it is possible that you will encounter additional errors when you run the application. For a list of known issues, see Troubleshooting Applications Upgraded from Visual Basic 6.0.

Upgrading Applications Created in Previous Versions of Visual Basic | Viewing the Upgrade Report | Preparing a Visual Basic 6.0 Application for Upgrading | WebClass Changes in Visual Basic .NET

Visual Basic 6.0 Code Upgrade Dialog Box

The **Visual Basic 6.0 Code Upgrade** dialog box is used to upgrade Visual Basic 6.0 code to Visual Basic .NET. Code can be typed into the **Code** window or pasted from the Visual Basic 6.0 Code Editor. When you click the **Upgrade** button, the upgraded code is inserted into the Visual Basic .NET Code Editor at the current cursor location.

In addition, COM references required by the Visual Basic 6.0 code can be added to the **References** tab; these are added to the References in your Visual Basic .NET project.

To access the **Visual Basic 6.0 Code Upgrade** dialog box, choose **Upgrade Visual Basic 6 Code** from the **Tools** menu.

> **Note** The **Upgrade Visual Basic 6 Code** command is only available when working in the Code Editor.

Code
Visual Basic 6.0 code can be typed into the code window or pasted from the Visual Basic 6.0 Code Editor. Code is retained between uses so that you can further modify the code if necessary.

References
Displays COM references required by Visual Basic 6.0 code that you have added.

Reference Name
Displays the friendly name of the COM component. Only references that are checked will be added to the Visual Basic .NET project.

Version
Displays the version number (major and minor) of the COM component.

Path
Displays the file path and filename for the COM component.

Add References
Displays the **Add Reference** dialog box that contains a list of available COM components.

Upgrade
Upgrades any code entered into the Code window and inserts it in the Visual Basic .NET Code Editor; also adds any checked references in the References list to the Visual Basic .NET project.

Upgrading Visual Basic 6.0 Code with the Upgrade Visual Basic 6 Code Dialog Box |
Upgrading Applications Created in Previous Versions of Visual Basic

Upgrading Visual Basic 6.0 Code with the Upgrade Visual Basic 6 Code Dialog Box

The Upgrade Visual Basic 6 Code dialog box is a tool that converts Visual Basic 6.0 code to equivalent Visual Basic .NET code. Unlike the Visual Basic Upgrade Wizard, which upgrades an entire application, the Upgrade Visual Basic 6 Code dialog box is available at design time to convert small amounts of code as you are developing your Visual Basic .NET application.

The Upgrade Visual Basic 6 Code dialog box is useful in two ways:

- You can make use of existing Visual Basic 6.0 code by pasting it into the tool.
- You can type in code using Visual Basic 6.0 syntax in order to learn the Visual Basic .NET equivalent.

After running the tool, Visual Basic .NET code is inserted into the Code Editor at the current cursor location. If there are any problems with the conversion, comments are inserted with clickable links to help topics that explain the problem and any possible workarounds.

To upgrade Visual Basic 6.0 code

1. In the Code Editor, move your cursor where you want to insert code.
2. On the **Tools** menu, choose **Upgrade Visual Basic 6 Code**.

   The **Visual Basic 6.0 Code Upgrade** dialog box will be displayed.

3. In the **Visual Basic 6.0 Code Upgrade** dialog box, paste in existing Visual Basic 6.0 code, or enter code using Visual Basic 6.0 syntax.
4. If your code references a COM component, select the **References** tab and click **Add Reference**, then select the reference in the **Add Reference** dialog box.
5. Click **Upgrade** to convert the code and insert it into the Visual Basic .NET Code Editor.

   Any COM references will be added to the References node for your project in Solution Explorer, and a project-level Imports statement will be added for the Microsoft.VisualBasic.Compatibility namespace.

Tips for Using the Upgrade Visual Basic 6 Code Dialog Box

The Upgrade Visual Basic 6 Code dialog box has some limitations; not all code can be successfully converted. The following tips can help you to get the most out of the tool.

- Not all Visual Basic 6.0 code is compatible with Visual Basic .NET. For more information about the limitations, see Things to Consider Before Upgrading.
- How your Visual Basic 6.0 code is written can have an effect on how it is upgraded. There are a number of recommendations that you can follow that will make your code easier to upgrade. For more information, see Language Recommendations for Upgrading.
- If the code does not run successfully in Visual Basic 6.0, it will not run in Visual Basic .NET. When pasting code from a Visual Basic 6.0 project, you should first test the code before attempting to upgrade.
- Event signatures in Visual Basic .NET are different than their Visual Basic 6.0 counterparts. When entering code for form or control event procedures, it is best to first add the procedure declaration in Visual Basic .NET and then upgrade only the body of the procedure.
- The Upgrade Visual Basic 6 Code dialog box is designed to upgrade small sections of code. It relies on the code typed into the dialog box to determine context for the upgrade.

  For example, the statement `L.Caption = "MyCaption"` would not be translated because the tool does not know what type "L" is, so it cannot resolve the property "Caption". Inserting a declaration for "L" (Dim L As Label) prior to the statement would result in a proper upgrade.

- Entering invalid Visual Basic 6.0 syntax can result in an "Untranslated statement in WrapperSub" error. If you see this error, inspect your code to make sure the syntax is correct.
- For best performance, upgrade code in modules rather than in Form modules. If you need to upgrade a form, use the Upgrade Wizard.

See Also

Upgrading WebClass Projects to Visual Basic .NET

Visual Basic 6.0 WebClass projects (also known as IIS Application projects) can be upgraded to ASP.NET Web Application projects using the Upgrade wizard. The process for upgrading WebClass projects is essentially the same as for any other project type; however, there are some issues that you will want to be aware of.

In order to upgrade a WebClass project, there are two prerequisites:

- Internet Information Services (IIS) must be installed and running on the upgrade computer
- You must have Administrative privileges that allow you to install applications.

When a WebClass project is upgraded, by default the project will be created with a new project name of *projectname*.NET (where *projectname* is the name of the Visual Basic 6.0 project). This name is then used when naming the virtual directory. This virtual directory will also be configured as an application in IIS; the Application Friendly name will be the *projectname*.

If the virtual directory name already exists on the http://localhost server (typical in a repeat upgrade scenario), a number will be appended to the virtual directory and project names in order to ensure uniqueness.

When a Visual Basic 6.0 WebClass project is upgraded to Visual Basic .NET, the .asp file for the project is upgraded to an .aspx file. Any references to the .asp file within an HTML template file are not automatically changed to .aspx references. These are not upgraded because a template file might contain references to other .asp files that were not part of the WebClass project.

In addition, when files are copied to the new project directory during upgrade, only HTML template files are copied. Any other .html files or image files are not copied to the new directory.

When adding HTML files to a Visual Basic .NET project, they are added as Content files by default. When a WebClass project is upgraded, HTML files are added as Embedded Resources. If you add HTML Files to the project after upgrading, you must set their **Build Action** property to **Embedded Resource** in order to make them visible to the application.

> **Tip** You can still reference an HTML file that is not embedded by providing a full path to the file when calling **WriteTemplate**.

If you have never created an ASP.NET Web Application before upgrading your first Visual Basic 6.0 WebClass project, you will need to set the Visual Basic .NET project's **StartUp** object by right-clicking the .aspx file and selecting **Set As Start Page** from the shortcut menu before running the upgraded project.

WebClass Changes in Visual Basic .NET | Upgrading Applications Created in Previous Versions of Visual Basic

Completing the Upgrading Process

After running the Upgrade Wizard, your upgraded project will be opened in Visual Studio .NET. The project will appear in Solution Explorer; it will include upgraded copies of all project files plus an upgrade report.

In most cases, there is additional work that will need to be done to ensure that your project will run successfully in Visual Basic .NET. There are three categories of work items that must be completed:

- UPGRADE_ISSUE errors are items that will prevent the application from compiling. You must correct these errors before running the project. These are reported in the upgrade report as and also appear as items in the Task List.
- UPGRADE_TODO errors are items that will not keep the project from compiling but that will cause run-time errors. You must correct these errors before running the project. These are reported in the upgrade report, as items in the Task List, and as comments in the upgraded code.
- UPGRADE_WARNING errors are items that will not keep the project from compiling but that may cause run-time errors. You should investigate these and correct them as necessary. These are reported in the upgrade report, as items in the Task List, and as comments in the upgraded code.
- UPGRADE_NOTE items are items that represent major changes to code or behavioral differences, which could have potential side effects. You should read these notes and decide if you need to make changes. These are reported as comments in the code.

To complete the upgrade process, you will need to check the Task List for any errors or warnings and search your code for any comments that begin with "UPGRADE_NOTE".

> **Tip** Every comment line inserted into your code during upgrade contains a hyperlink. Clicking the link (CTRL+click) takes you to a Help topic that explains the issue and what you need to do to address it. The link appears at the end of the comment line; you may need to scroll in order to see it.

Visual Basic Upgrade Report | Task List Window | Searching and Replacing | Visual Basic Upgrade Wizard | Upgrading Applications Created in Previous Versions of Visual Basic

Visual Basic Upgrade Report

When a Visual Basic 6.0 project is upgraded to Visual Basic .NET, an upgrade report is added to the project in Solution Explorer. The upgrade report contains information about the upgrade process as well as a list of issues uncovered during the upgrade that will need to be addressed before your project can be run.

The upgrade report is in HTML format; you can view it within the Visual Studio .NET development environment by double-clicking the file in Solution Explorer, or you can view it in an external browser by choosing **Browse With** from the **File** menu.

The first portion of the report contains general information about the upgrade, including the settings that were used during the upgrade and the location of the new project files.

The remainder of the report contains a listing of global issues plus a listing for each file that was upgraded. By expanding the section for each file, you can view a detailed list of issues that will need to be addressed. Each issue includes information about the severity of the issue, the location of the code that must be fixed, and a description of the issue.

Completing the Upgrading Process | Visual Basic Upgrade Wizard |
Upgrading Applications Created in Previous Versions of Visual Basic

Viewing the Upgrade Report

When a Visual Basic 6.0 project is upgraded to Visual Basic .NET, an upgrade report is created and placed in the new project folder. The upgrade report contains summary information about the upgrade process plus information on any errors or issues encountered during upgrade.

> **Note** The upgrade report is only generated for projects upgraded using the Upgrade Wizard; no reported is generated for projects upgraded from the command line.

The upgrade report can be viewed in the Visual Studio .NET integrated development environment (IDE) or in any Web browser.

To view the upgrade report in Visual Studio .NET

- In Solution Explorer, double-click the **_UpgradeReport.htm** node to open the upgrade report.

To view the upgrade report in a Web browser

1. In Solution Explorer, select the **_UpgradeReport.htm** node.
2. On the **File** menu, choose **Browse With**.
3. In the **Browse With** dialog box, select the Web browser.

Upgrading Applications Created in Previous Versions of Visual Basic | Preparing a Visual Basic 6.0 Application for Upgrading

Upgrading a Project from the Command Line

In addition to the Visual Basic Upgrade Wizard, Visual Basic 6.0 projects can be upgraded to Visual Basic .NET using a command-line tool, Vbupgrade.exe.

> **Note** Vbupgrade.exe is not on the path by default. You will need to either add it to the path or switch to the directory where it is installed before running it from the command line. The default installation location is C:\Program Files\Microsoft Visual Studio .NET 2003\Vb7\VBUpgrade.

To upgrade a project from the command line

1. Open your project in Visual Basic 6.0. On the **File** menu, choose **Make *projectname***. Run the application and make sure that there are no errors.
2. At a command prompt, type **Vbupgrade *projectname*** (where *projectname* is the full path for the Visual Basic 6.0 application) plus any additional command-line arguments.

   > **Note** For information on Vbupgrade command-line syntax and options, see Vbupgrade Command-Line Syntax.

3. Open the resulting project in Visual Studio .NET. Review the code — notes are inserted into the code during upgrade to alert you to any potential problems. Any errors must be fixed before you can run the application. Any warnings should be examined to make sure that they do not affect application behavior.

   > **Tip** For an explanation of any error or warning, click on the description to display a Help topic.

4. On the **Debug** menu, choose **Start.** Run the application and make sure that there are no errors and that the behavior is the same as it was in Visual Basic 6.0.

   > **Note** The Vbupgrade tool cannot catch all possible incompatibilities; it is possible that you will encounter additional errors when you run the application. For a list of known issues, see Troubleshooting Applications Upgraded from Visual Basic 6.0.

Vbupgrade Command-Line Syntax | Upgrading Applications Created in Previous Versions of Visual Basic | Viewing the Upgrade Report | Preparing a Visual Basic 6.0 Application for Upgrading

Vbupgrade Command-Line Syntax

The Vbupgrade.exe command-line tool can be used to upgrade a Visual Basic 6.0 application to Visual Basic .NET.

The command line syntax for Vbupgrade.exe is:

```
Vbupgrade[.exe] inputname [/Out outputname] [/Verbose [/NoLog [/LogFile logfilename]]]
Vbupgrade[.exe] /?
```

inputname
Required.

Specifies the path and file name of the Visual Basic 6.0 project to be upgraded.

/Out *outputname*
Specifies the path for the folder where the Visual Basic .NET project will be created. The default path is \OutDir.

/Verbose
Displays all output to the DOS window during upgrade.

/NoLog
Does not create a log file during upgrade.

/LogFile *logfilename*
Specifies the path and file name for the log file created during upgrade. If the path and file name are not specified, a log file will be created in the same folder as the Visual Basic .NET project. The default file name is *ProjectFileName*.log, where *ProjectFileName* is the name of the project file.

/?
Displays a list of command-line options.

Remarks

Paths or file names that contain spaces must be surrounded by quotation marks.

Troubleshooting Applications Upgraded from Visual Basic 6.0

Although the upgrading tools in Visual Basic .NET were carefully designed to detect and report any issues with upgraded applications, there are some cases that cannot possibly be detected. This topic lists some known issues that are not detected by the upgrading tools and explains how to address them.

> **Note** Additional troubleshooting issues are addressed in a Knowledge Base article that will be updated as new issues are discovered. The article number is Q295626, available at Microsoft Product Support Services (http://support.microsoft.com/directory/content.asp?ID=FH;EN-US;vbdnmig).

Cannot Access Help Links After Upgrading Visual Studio .NET

When working with an application upgraded with an earlier version of Visual Studio .NET, the Help links inserted by the upgrade tool may cause a "Page not found" error. This occurs because the links reference the Help collection for the earlier version, and that Help collection was uninstalled.

To fix this problem, use the Find and Replace command on the Edit menu to search for the string "MS.VSCC" and replace it with "MS.VSCC.<VersionNumber>" (for example, "MS.VSCC.2003" for Visual Studio .NET 2003) in all of the Help links.

Behavioral Difference for Fixed-length Strings in User-defined Types

In Visual Basic 6.0, strings assigned to a fixed-length string in a user-defined type were automatically truncated if they were longer than the fixed length. After upgrading to Visual Basic .NET, strings will no longer be truncated, possibly resulting in incorrect results.

> **Note** During upgrade, the **VBFixedString** attribute is added to fixed-length strings in user-defined types. This attribute allows the file functions in the Visual Basic Compatibility library to treat them as fixed-length strings.

To fix this problem, find any code that assigns a string to the fixed-length string and add code to check the length of the string and truncate it if necessary:

```
' Before
MyString = "1234567"
MyStruct.FixedString5 = MyString

' After
MyString = "1234567"
If Len(MyString) > 5 Then
   MyString = Microsoft.VisualBasic.Left(MyString, 5)
End If
MyStruct.FixedString5 = MyString
```

Closing a Form Calls Dispose

In Visual Basic 6.0, you could unload a form and later reload it by calling the **Show** method. In Visual Basic .NET, the **Close** method for a form calls the **Dispose** method so that it is automatically garbage-collected. This can cause subtle behavioral differences that may be hard to detect.

- In Visual Basic .NET, if you call the **Show** method for a form that has been unloaded, you will get a new instance of the form; any property settings from the base class will be lost.
- For forms that are shown modally, **Dispose** is not called automatically. In some cases, you may want to call **Dispose** in order to clean up resources.

Late-bound Calls to COM Objects May Cause Type Mismatch Errors

In Visual Basic 6.0, when a late-bound COM object was passed as a parameter to a late-bound call, the object was coerced to a **Variant** of type **Nothing**. When upgraded to Visual Basic .NET, COM objects declared as type **Object** are treated the same as **Variants** (which are always converted to type **Object** during upgrade); these objects are marshaled to the variant type **Empty**. This causes a type mismatch error in Visual Basic .NET.

To fix this problem, make sure that all objects are early bound.

Values Returned by Err.Number May Be Different

In some cases, errors returned by Visual Basic .NET may be different than those returned by Visual Basic 6.0. For error handling code that relied on the values returned by **Err.Number**, this might cause different behavior in your application.

The following code shows an example of this:

```
' Visual Basic 6.0
On Local Error GoTo Result
Dim x() As Boolean
Dim y As Variant

y = x(10)

Result:
If Err.Number = 9 Then
   ' Do something.
Else
   ' Do something else.
End If
```

Before upgrading, **Err.Number** will always return 9 (Subscript out of range) and execute the first part of the **If** statement. After upgrading, it will return 91 (Object variable or With block not set) and execute the **Else** clause. This is because in Visual Basic .NET, an array must be initialized before it can be referenced; in Visual Basic 6.0, arrays were initialized when declared.

If you depend on the return values from **Err.Number** in your code, you should carefully test the results and modify your code as necessary.

Dispose Must Be Explicitly Called for a DataEnvironment

In Visual Basic 6.0, any open recordsets and connections were closed when a **DataEnvironment** was closed. When upgraded to Visual Basic .NET, the DataEnvironment becomes a Public member of the **DataEnvironment** class; recordsets and connections are not automatically closed.

You will need to add code to explicitly close the recordsets and connections by calling the **DataEnvironment.Dispose** method. For Windows Forms applications you can call the **Dispose** method from the startup form's **Dispose** method. For class libraries, you will need to implement a **Dispose** method on your class library then have the client application call **Dispose** before it releases it's reference to the class.

Upgrading Applications Created in Previous Versions of Visual Basic | Working with Both Visual Basic 6.0 and Visual Basic .NET

Working with Both Visual Basic 6.0 and Visual Basic .NET

Both Visual Basic .NET and Visual Basic 6.0 can be installed on the same computer and run at the same time. Likewise, applications written in Visual Basic .NET and Visual Basic 6.0 can be installed and run on the same computer. Components written in Visual Basic .NET can interoperate with COM components written in earlier versions of Visual Basic and other languages. For example, you can drag an ActiveX control written in Visual Basic 6.0 onto a Visual Basic .NET Windows Form, use a Visual Basic 6.0 COM object from a Visual Basic .NET class library, or add a reference to a Visual Basic .NET library to a Visual Basic 6.0 executable.

Components compiled with Visual Basic .NET have subtle run-time differences from components compiled with Visual Basic 6.0. Because Visual Basic .NET objects are released through garbage collection, when objects are explicitly destroyed there may be a lag before they are actually removed from memory. There are additional differences such as data type and other language changes. The combined result of these differences is that Visual Basic .NET applications will have similar but not identical run-time behavior to Visual Basic 6.0 applications.

In addition, Visual Basic .NET makes binary compatibility between Visual Basic .NET components and those in Visual Basic 6.0 unnecessary. Components now have a more robust versioning and deployment system, files can be deployed by simply copying to a directory, and upgrading to a new version of a component is as simple as replacing the old file with a new file. All you have to do is ensure classes and methods are compatible with the previous version.

Why Upgrading is Necessary | Preparing a Visual Basic 6.0 Application for Upgrading |
Upgrading Applications Created in Previous Versions of Visual Basic

Walkthrough: Upgrading a Visual Basic 6.0 Application to Visual Basic .NET

In this walkthrough, you will upgrade a Visual Basic graphics sample application to Visual Basic .NET. In addition to illustrating the upgrading process, this walkthrough highlights the differences in graphics architectures between Visual Basic 6.0 and Visual Basic .NET. This should also serve as an introduction to dealing with architectural issues in your applications.

The sample application in this case is a simple form that contains two buttons, a picture box, a timer, and a hidden image control. Although not typical of most applications that you will want to upgrade, it does present several challenging issues that you may face when upgrading your own applications.

> **Note** This walkthrough requires that both Visual Basic 6.0 and the Drawing.vbp sample application be installed on your development computer. The sample application can be installed from the Visual Studio .NET CD; the default location is Program Files\Microsoft Visual Studio .NET 2003\Vb7\VB Samples\MigrationWalkthrough.

To familiarize yourself with the application

1. In Visual Basic 6.0, open the **Drawing.vbp** project file (on the **File** menu, choose **Open Project**).
2. On the **Run** menu, choose **Start**. Click the buttons, and observe the run-time behavior and appearance of the application.
3. On the **Run** menu, choose **End** to close the application.
4. In the Project Explorer, select **Form1(PicForm.frm)**. On the **View** menu, choose **Object**. Observe the design-time layout of the form.
5. On the **View** menu, choose **Code**. Familiarize yourself with the application's code.

   > **Tip** If you do not understand how the code works, try stepping through the code by choosing **Step Into** on the **Debug** menu.

6. On the **File** menu, choose **Exit** to close the application. If prompted to save changes, choose **No**.

To run the Upgrade wizard

1. Open Visual Studio .NET. On the **File** menu, choose **Open**, **Project**.
2. In the **Open Project** dialog box, locate the **Drawing.vbp** file and open it.

   This will launch the Visual Basic Upgrade Wizard. The first page of the wizard contains an explanation of what the wizard will do.

3. Click **Next** to go to the second page of the wizard. This page presents options for upgrading; in this case, there are no applicable options available.
4. Click **Next** to go to the third page of the wizard. Click **Next** to accept the default location for the new project, or enter a different location. The default location is a new folder immediately beneath the Visual Basic 6.0 project's folder.

   If prompted to create a new folder, choose **Yes**.

5. On the fourth page of the Wizard, click **Next** to begin the upgrade.

   When the upgrade is finished, the wizard will close and the new project will appear in Solution Explorer.

To view the upgrade results

1. In Solution Explorer, select **_UpgradeReport.htm** and double-click to open the Upgrade Report.

   Note that the report shows no Global Issues that need to be addressed; for PicForm.vb it shows six errors and no warnings.

   > **Note** If there were warnings, they would also appear in the Task List window as UPGRADE_WARNING items. Warnings are for code that might cause subtle differences in the run-time behavior of your application. Double-clicking an UPGRADE_WARNING in the Task List window will take you directly to the code that may need to be modified.

2. Expand the **PicForm.vb** section by clicking on the plus sign in the **New Filename** column. This displays a detailed list of upgrade issues for the form.

   Note that the issues apply to three different locations: the **ClearPictureBox_Click** procedure, the **Timer1_Timer** procedure, and the form layout. You can click on the **Description** link to display a Help topic explaining each issue. The layout issues in

this case do not require any action; checking the Help reveals that they are for two properties of the Visual Basic 6.0 **PictureBox** control that do not map to equivalent Visual Basic .NET properties

To fix the ClearPictureBox_Click error

1. In Solution Explorer, select **PicForm.vb**. On the **View** menu, choose **Code**.
2. In the Code Editor, select the **ClearPictureBox_Click** procedure.

   Tip There is an UPGRADE_ISSUE comment added to the procedure. If you scroll to the end of the comment, you can click on the link that displays the associated Help topic. All issues (except for layout issues) are added as code comments during upgrade, including UPGRADE_NOTE comments explaining what happened during upgrade; these do not appear in the Upgrade Report.

3. Add the following code to the **ClearPictureBox_Click** procedure:

```
Dim g as Graphics = Picture1.CreateGraphics()
g.Clear(Picture1.BackColor)
g.Dispose()
```

   The only error in the original procedure is the **Picture1.Cls()** method call. In Visual Basic .NET the intrinsic controls do not provide direct access to their drawing surfaces with methods (as in Visual Basic 6.0). All graphics operations are handled with a special object of type **Graphics**. You can access a control's drawing surface by calling the **CreateGraphics()** method to get an instance of a **Graphics** object.

4. Delete or comment out the original line `Picture1.Cls()`.

To fix the Timer1_Timer errors

1. In the Code Editor, select the **Timer1_Tick** procedure.

   Note The **Timer** event from the Visual Basic 6.0 **Timer** control is upgraded to the **Tick** event of the Visual Basic .NET **Timer** component. The Upgrade Report shows the old event name; the Code Editor uses the new event name.

2. At the start of the function add the following code:

```
Dim g as Graphics = Picture1.CreateGraphics()
```

   As with the previous procedure, the errors here begin with the lack of a **Graphics** object.

3. Find the first UPGRADE_ISSUE, the **Picture1.Print** method. Add the following code:

```
g.DrawString("VB .NET ROCKS!",  Me.Font, new SolidBrush(Color.Yellow), 0, 0 )
```

   The **DrawString** method of the **Graphics** object replaces the Visual Basic 6.0 **Print** method. Where the **Print** method took a single **Text** argument, **DrawString** also takes arguments specifying the **Font**, a **Brush** object that specifies a **Color** object, and the starting coordinates for drawing the text.

4. Delete or comment out the original line `Picture1.Print("Visual Basic ROCKS!")`.
5. Find the next UPGRADE_ISSUE, **Picture1.Cls()**. Replace the code with the following:

```
g.Clear(Picture1.BackColor)
```

6. Find the last UPGRADE_ISSUE, **Picture1.PaintPicture**. Add the following code:

```
g.DrawImage(sourceImage.Image, CSng(LeftPos * Picture1.Size.Width), 0)
```

   In this case, the **DrawImage** method of the **Graphics** class replaces the **PaintPicture** method.

7. Delete or comment out the original line `Picture1.PaintPicture(sourceImage, LeftPos * VB6.PixelsToTwipsX(Picture1.Width), 0)`.
8. At the end of the procedure, add the following code:

```
g.Dispose()
```

The **Dispose** method is necessary to free up the memory resources associated with the **Graphics** object.

To test the application

1. On the **Debug** menu, choose **Start**.

   Note The first time you run the application, you will be prompted to save the Solution file. Click **Save** to save the file and run the application.

2. Click the **ShowImage** button.

   You will notice that the image flickers when drawing. This is due to the entire area being cleared before each updated image is drawn on the screen.

The solution here is to only draw to the necessary parts of the screen, instead of the entire area represented by the **Graphics** object. You will want to make sure that when the image is drawn on the screen, any pixels remaining on the screen from the last call to **DrawImage()** are obscured with the background color. Since the image is moving from right to left, you only have to obscure the additional pixels to the right of the picture.

To fix the screen flicker problem

1. In the **Timer1_Tick** procedure, replace the `g.Clear(Picture1.BackColor)` method with the following code:

```
Dim imageWidth As Integer = sourceImage.Image.Width
Dim imageHeight As Integer = sourceImage.Image.Height
Dim left As Integer = imageWidth + (Picture1.Size.Width * LeftPos)

g.FillRectangle(New SolidBrush(Me.BackColor), New Rectangle(left, 0, 6, imageHeight))
```

   In place of the **Clear** method, you use the **FillRectangle** method, using the background color to obscure any remaining pixels to the right of the current image being drawn. To do this, you first need to calculate the left-most coordinate of the rectangle, which is accomplished by the first three lines of code.

2. On the **Debug** menu, choose **Start**.
3. Click the **ShowImage** button.

   You will notice that the image no longer flickers as it moves.

There is still one additional problem that should be fixed. You may have noticed that the message displayed in the **PictureBox** control is in a smaller font than the original version. This is because the **Font** property of the **PictureBox** control in the Visual Basic 6.0 application was set to Arial Bold 16 at design time. There is no **Font** property for the Visual Basic .NET **PictureBox** control, so instead the form's default font (`Me.Font`) is used. You can remedy this by declaring a new **Font** object.

To fix the font

1. In the **Timer1_Tick** procedure, add the following declaration:

```
Dim f As System.Drawing.Font = New System.Drawing.Font("Arial", _
16, FontStyle.Bold)
```

2. In the call to `g.DrawString`, change the font parameter from `Me.Font` to `f`.
3. On the **Debug** menu, choose **Start**.
4. Click the **ShowImage** button.

   The text is now displayed in the correct font.

Now that the application is back to parity with the original Visual Basic 6.0 application, you will add some code to enhance the application. After all, there is no point in upgrading the application if you do not want to take advantage of Visual Basic .NET.

In the next step, you will add functionality to make the form fade out slowly when it is closed.

Note The fade effect is not visible on 256-color displays; you will need to set your color depth to High Color or True

Color to view the results. The **Opacity** property only works on Windows XP.

To enhance the application

1. In the Code Editor, select the **Class Name** drop-down list and choose **(Base Class Events)**.
2. In the **Method Name** drop-down box, select the **Closing** event.
3. In the **Form1_Closing** procedure, add the following code:

```
Dim i as Single
For i = 1 to 0 Step -0.1
   Me.Opacity = i
   Application.DoEvents()
   System.Threading.Thread.Sleep(100)
Next
```

4. On the **Debug** menu, choose **Start**.
5. Close the form and notice how it fades away.

   You can control how fast it fades by increasing the size of the step (or by reducing the Sleep delay).

Upgrading from Visual Basic 6.0 | Introduction to Windows Forms | Graphics Changes in Visual Basic .NET

Upgrading Visual InterDev 6.0 Applications to Visual Studio .NET

If you have existing Visual InterDev projects, you might want to upgrade them to Visual Studio .NET. Although you cannot open a Visual InterDev project in Visual Studio .NET, there are features in Visual Studio .NET that will allow you to make a smooth transition from Visual InterDev.

> **Note** Upgrading Visual Interdev 6.0 applications to Visual Studio .NET 2003 is not supported.

There are two possible ways to work with an existing Visual InterDev application in Visual Studio .NET:

- **Creating a new Web project** to interact with an existing Visual InterDev application. This will create all of the extra files needed by your new Web application, in addition to creating the new project. You can then move files into your new Web application as you upgrade them. This approach is recommended when you want to have all the associated files created for you at the time you create the new Web project.

  > **Note** This is the recommended path for upgrading a project that is under source control with Visual SourceSafe. This will effectively fork your history, and you will be unable to access previous versions of your Visual InterDev project as part of your Visual Studio .NET project.

- **Creating a new project in your existing folder**. One way to begin your project transition is by using the New Project in Existing Folder template. That template allows you to create a new Visual Studio .NET project in an existing folder. From there you can add your existing Visual InterDev files to your new project and upgrade them as needed. This approach creates only a new project, and does not create any of the associated files you will need to run your new Web application, such as the Web.config file. Therefore, it is recommended that you use this approach when you want to manually upgrade any configuration data to your new Web application. Do not use this method to upgrade a project that is under source control with Visual SourceSafe.

  > **Note** The New Project in Existing Folder template is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

HTML files can be transferred from Visual InterDev projects to Visual Studio .NET projects without any loss of functionality. ASP pages will also continue to function, although it is recommended that you upgrade your ASP pages to ASP.NET in order to take advantage of the rich new array of features that the .NET Framework provides. Design-time controls (DTCs) are no longer supported, and new solutions will have to be developed to accommodate any loss of functionality. There is currently no tool for migrating ASP to ASP.NET, so you will have to upgrade your Web projects manually. For more information on migrating ASP pages to ASP.NET, see Migrating ASP Pages to Web Forms Pages. For more information on creating Web Applications, see Creating Web Applications and Services.

To upgrade your project to Visual Studio .NET

1. Open Visual Studio .NET.
2. From the **File** menu, choose **New** and then choose **Project**.

   The **New Project** dialog box appears.

3. Select either **Visual Basic Projects** or **Visual C# projects**, depending upon which language you want to use. For more information, see Programming Languages.
4. Enter the name for the new project in the **Name** box.
5. Decide whether you need to manually create upgrade-configuration data.

   - If you want to automatically create new configuration data, select **ASP.NET Web Application.**

     - or -

   - If you want to manually upgrade configuration data, double-click the **New Projects In Existing Folder** project template.

     > **Note** You must specify the HTTP path to the existing project. If you specify the file path, a Windows project will be created instead of a Web project.Al

     > **Caution** Do not use this method to upgrade a project that is under source control with Visual

SourceSafe.

6. Browse to the folder that contains your **Visual InterDev** project and select it.
7. In Solution Explorer, right-click the new project and select **Add** from the shortcut menu, then **Add Existing Item**.

   The **Add Existing Item** window opens.

8. Click the drop-down list on the **Files Of Type** box and select **All Files**.

   All files in the folder will be shown.

9. Select the files from your Visual InterDev project that you want to add to your Visual Studio .NET project.

Managing Projects

The project is the starting point for authoring applications, components, and services in Visual Studio .NET. It acts as a container that manages your source code, data connections, and references. A project is organized as part of a solution, which can contain multiple projects that are interdependent of each other. The topics in this section describe the various tasks involved in creating and managing Visual Basic and Visual C# projects.

In This Section

Local vs. Web Projects
Explains the essential differences between these two project models.
File Properties
Describes property settings that indicate what actions the project system should perform on the files.
Visual Basic and Visual C# Projects
Provides a list of the types of projects that can be created with project templates.
Referencing Namespaces and Components
Provides links to topics about adding, removing, fixing, and managing project references.
Working with Web Projects
Provides links to topics about tasks involved in working with Web projects.
Resource File Naming Conventions
Provides links to information about XML and non-XML assembly-manifest resource files.
Configuring Applications Using Dynamic Properties
Describes how to configure your projects so that some project properties are stored to a configuration file instead of inside the compiled code.

Related Sections

File Types and File Extensions in Visual Basic and Visual C#
Lists and describes the file extensions for all files available in Visual Basic and Visual C# projects.
Project Changes in Visual Basic .NET
Summarizes how projects are different than they were in Visual Basic 6.0.
Visual Basic Code Example Topics
Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.
Decision Chart
Provides a graphical, linked guide to decisions about designing your application.
Debugging
Describes how to resolve logic and semantic errors by using the Visual Studio Debugger.
Tracing and Instrumenting Applications in Visual Basic and Visual C#
Describes how to monitor the execution of your application while it is running.
Build Configurations
Describes options for building and deploying solutions and projects.
Default and Custom Builds
Gives an overview of creating standard and custom builds from within the IDE.
Devenv Command Line Switches
Provides the standard command line switches for Visual Studio.
Visual Basic Compiler Options
Provides compiler command line options for Visual Basic.
C# Compiler Options
Provides compiler options for Visual C#.
Refreshing Items in Solution Explorer
Describes how to incorporate changes made by other users into your project.
What's New in Projects
Lists and briefly describes the major new Visual Basic project features, including deployment projects.
Adding New Project Items
Provides step-by-step instructions on adding new project items.
Introduction to Solutions, Projects, and Items
Gives an overview of solutions and projects.
Deployment Projects
Recommends which kind of deployment project to use for your application or component.
Removing, Deleting, and Excluding Items
Provides instructions for how to remove, delete, or exclude items in Visual Studio.

Setting Visual Basic Project Properties

Provides step-by-step instructions on how to access project properties.

Setting Visual C# Project Properties

Provides descriptions of Visual C# project property settings.

Programming with Office

Provides information on using Microsoft Office and Visual Studio .NET as part of your business application.

Working with Multiple Versions of the .NET Framework

By default, managed applications created with Visual Studio .NET 2003 or later require version 1.1 of the common language runtime in order to run. There may be some cases where you want your application to target an earlier version of the runtime. For example, if all of your customers have already installed runtime version 1.0 and deploying version 1.1 is not feasible, you may want to target version 1.0.

> **Note** Although it is possible to target version 1.0 of the common language runtime from Visual Studio .NET 2003, it is highly recommended that you use Visual Studio .NET 2002 for that instead. You can install and run both versions side-by-side on the same computer. For more information, see Installation and Setup.

> **Caution** Targeting a previous version of the runtime could cause the application to fail if it references .NET Framework classes or members that did not exist in the previous version. You should thoroughly test your application against all specified versions to make sure that it runs properly. For more information on the differences between version 1.0 and 1.1, see What's New in the .NET Framework Version 1.1.

Visual Studio .NET 2003 projects use the **Supported Runtimes** property to specify the required versions of the common language runtime. This property is only available for Windows Application, Windows Service, Console Application, and ASP.NET Web Application projects.

The **Supported Runtimes** property can be set in the **Project Property Pages** dialog box. For more information, see Specifying the Runtime Version for An Application.

> **Note** When you specify version 1.0, the app.config file will be modified with a section specifying that it can run on version 1.0 of the runtime. The application will actually be built using the version 1.1 compiler, and will be a version 1.1 application in all other respects.

In the event that you specify support for than one runtime version, when the application runs on a computer with more than one runtime version installed, the first available version listed in the .config file will be loaded.

Windows Application, Windows Service, or Console Application Projects

For these project types, selecting a runtime causes the project system to update the app.config file in your project, or create an app.config file if one does not already exist. At run time, the name of the app.config file must be *filename.ext*.config and the file must be in the same directory as the executable. The project system will create the *filename.ext*.config file from the app.config file and place it in the bin*target* directory.

ASP.NET Web Application Projects

For ASP.NET Web Application projects, modifying this property causes the project system to update the web.config file in your project by adding assembly binding (<bindingRedirect> and <assemblyIdentity>) tags in a <dependentAssembly> section. Web pages in Visual Studio-built ASP.NET web applications are precompiled to a .dll with a dependency on the runtime associated with the compiler.

The web.config file remains in the project directory and is not renamed.

For more information, see ASP.NET Side-by-Side Overview

See Also

Specifying the Runtime Version for An Application | Side-by-Side Execution | ASP.NET Side-by-Side Overview

Projects and Backward Compatibility

When a project created in Visual Studio .NET 2002 is opened in Visual Studio .NET 2003 or later, you are prompted with a warning that the project file will be updated. After you open the project, you will no longer be able to open it in the earlier version.

The versions of Visual Studio .NET rely on different versions of the common language runtime — for example, 1.0 for Visual Studio .NET 2002 and 1.1 for Visual Studio .NET 2003. After an application has been built against version 1.1, it requires that version 1.1 be present on a target computer in order to run.

Applications built using version 1.0 will continue to run with either runtime version.

> **Note** Using Visual Studio .NET 2003 or later, it is still possible to create applications that target runtime version 1.0 using the **Supported Runtimes** property. For more information, see Working With Multiple Versions of the .NET Framework.

See Also

Working With Multiple Versions of the .NET Framework | Side-by-Side Execution

Specifying the Runtime Version for an Application

Applications created in Visual Studio .NET 2003 or later can be set to target one or more versions of the common language runtime by setting the **Supported Runtimes** property. By default, the latest version of the common language runtime is used; specify a different runtime version if you want your application to run on a previous version of the common language runtime.

> **Caution** Selecting a previous version of the runtime could cause the application to fail if it references .NET Framework classes that did not exist in the previous version. You should thoroughly test your application against all specified versions. For more information, see Working With Multiple Versions of the .NET Framework.

To specify the runtime version in Visual Basic .NET

1. Select the project in Solution Explorer.
2. On the **Project** menu, choose **Properties**.
3. In the **Property Pages** dialog box, select the **Build** node and click the **Change** button.
4. In the **.NET Framework Version** dialog box, select a version option and click **Update**.

To specify the runtime version in Visual C# .NET

1. Select the project in the Solution Explorer. On the **Project** menu, choose **Properties**.
2. In the **Property Pages** dialog box, select the **Supported Runtimes** property and click the Ellipsis (...) button.
3. In the **.NET Framework Version** dialog box, select a version option and click **Update**.

Local vs. Web Projects

There are several factors to consider when you decide whether to use a local or Web project model for your application.

First, installation strategy should play a part in your overall decision. If you need a quick-deploying application on a server with minimal client configuration, the Web project model is best. You can install and run this project on the server without installing support files on each client, and make upgrades only on the server. However, for projects that have little server involvement or for stand-alone applications, a local project model is the better choice. In this scenario, upgrades can be completed on each individual client computer.

Another factor is the division of workload. When analyzing your application's framework, you need to consider where the bulk of the work is going to be done. Web projects offer a server-based strategy where the majority of operations are conducted on the server. The client computer uses a Web browser to send information to and display information from the server-side application. If your server resources are limited, then consider using a local project model for your application. The work can be done on the client computer without consuming precious server time.

The following table gives a side-by-side comparison of Web projects and local projects in both the design and working environments:

Consideration	**Web project**	**Local project**
File storage during development	Files are stored at a specified URL on a computer with Internet Information Services (IIS) installed. The project also keeps a temporary cache of files on client computers for working offline.	Project files are stored on the local computer.
Build model when developing	Application code is compiled as a DLL and run on the server. Results are seen on the client computer.	Code is compiled and run on the client computer.
Deployment method	The project is deployed to a Web server.	Project files are installed on the client computer with required support files.
Workload	Client computers run the application remotely with a Web browser. Processing is done primarily on the server.	The application is run locally on the client computer.
Upgrading	Application changes are made at the server level without installation of support files on client computers.	The application upgrades are installed on client computers.
Moving project files	The Copy Project command is used to move files to the specified URL.	Project files are physically copied from one location to another.

File Properties

You can use file properties to indicate what actions the project system should perform on the files. For example, you can set file properties to indicate whether a file should be compiled or embedded into the build output as a resource.

You can select any file in Solution Explorer and then examine its properties in the Properties window. Visual Basic and Visual C# files have four properties: **FileName**, **BuildAction**, **CustomTool**, and **CustomToolNamespace**.

> **Note** The **BuildAction**, **CustomTool**, and **CustomToolNamespace** properties are provided for advanced scenarios. The default values are typically sufficient and do not need to be changed.

FileName Property

You can rename a file by clicking the FileName property in the Properties window and typing in the new name. Note that if you change the file's name, Visual Studio .NET will automatically rename any .vb or .resx files that are associated with it.

BuildAction Property

The BuildAction property indicates what Visual Studio .NET does with a file when a build is executed. **BuildAction** can have one of several values:

- **None** - The file is not included in the project output group and is not compiled in the build process. An example is a text file that contains documentation, such as a Readme file.
- **Compile** - The file is compiled into the build output. This setting is used for code files.
- **Content** - The file is not compiled, but is included in the Content output group. For example, this setting is the default value for an .htm or other kind of Web file.
- **Embedded Resource** - This file is embedded in the main project build output as a DLL or executable. It is typically used for resource files.

The default value for **BuildAction** depends on the extension of the file you add to the solution. For example, if you add a Visual Basic project to Solution Explorer, the default value for **BuildAction** is **Compile**, because the extension .vb indicates a code file that can be compiled. File names and extensions appear in Solution Explorer.

Note that the name of the file in your project will not be the identifier for the managed resource in the assembly manifest (see Assembly Manifest for more information). The identifier will be *namespace.filename.extension*, where *namespace* is the value of the **DefaultNamespace** property in a Visual C# project or **RootNamespace** property in a Visual Basic .NET project. *Filename* and *extension* remain the same as their original designation. If the file is a .resx file, the project system will run resgen.exe on the file, creating a .resource file. The .resource file will be embedded in the assembly, so the assembly manifest will refer to the .resources file and not the .resx file.

For example, if you add the file MyFile.bmp to a project whose default namespace is MyProj, and set the build action to **Embedded Resource**, MyProj.MyFile.bmp will be the identifier in the assembly manifest. If you then add the file MyFile.resx to the project, the default build action will be **Embedded Resource** and, MyProj.MyFile.resources will be the identifier in the assembly manifest.

For more information on how to access resource files (compiled from .resx files) at run time, see ResourceManager Class. For more information on how to access all other embedded files and resources at run time, see Assembly.GetManifestResourceStream Method.

CustomTool Property

Custom tools are components that can be used to transform files from one type to another at design time. For example, a custom tool might be a dataset code generator that reads in an XML Schema (.xsd) file, and generates classes in a code file that programmatically exposes its tables and columns. There is a predefined list of custom tools available in the product; this property allows you to see which custom tool is applied to a file. In rare circumstances, you might need to change the value of this property. The value of this property must either be blank or one of the built-in custom tools.

To set or change the custom tool, click the CustomTool property in the Properties window and type in the name of a custom tool.

CustomToolNamespace Property

If you have a custom tool assigned to your project, the CustomToolNamespace property allows you to specify the namespace you want to assign to code generated by the custom tool. When you specify a value for the **CustomToolNamespace** property, code generated by the tool is placed in the specified namespace. If the property is empty, generated code is placed in the default

namespace for the folder in which the converted file lives; for Visual Basic, this is the project's root namespace, and for Visual C# this corresponds to the setting of the DefaultNamespace property for the folder.

Setting Visual Basic Project Properties

You specify global settings for your project by using project properties. These default settings control the appearance and behavior of the items in your project throughout its life cycle. Properties are saved in the project's .vbproj file, and can be accessed through the **Property Pages** dialog box.

To access project properties

1. With a project selected in Solution Explorer, click **Property Pages** on the **View** menu.

   Notice the two folders in the project's **Property Pages** dialog box: **Common Properties** and **Configuration Properties**. Only the properties in **Configuration Properties** can be set by project configuration.

2. Select the **Configuration Properties** folder. Using the **Configuration** drop-down list, select the configuration for which you want to set this project's properties.

   If you have the **Common Properties** folder selected, the **Configuration** drop-down list is unavailable.

3. In the left pane, select a folder and property page.
4. In the right pane, set the available properties.

   > **Note** Properties that are dimmed are defined when the project is created; they are displayed for information only.

Getting Help on Properties

Documentation is available for each property page by simply clicking the **Help** button.

For a list of property pages available in a Visual Basic project, see <Projectname> Property Pages Dialog Box.

See Also

<Projectname> Property Pages Dialog Box

Setting Visual C# Project Properties

A project's properties specify how a project is built and debugged.

Accessing Project Properties

Visual C# property pages are only available when the project is selected in Solution Explorer; property pages are not available for individual files for a Visual C# project. However, you can access a file's properties in the **Properties** window.

To access project properties

1. With a project selected in Solution Explorer, click **Property Pages** on the **View** menu.

   Notice the two folders in a Visual C# project's **Property Pages** dialog box: **Common Properties** and **Configuration Properties**. Only the properties in **Configuration Properties** can be set by project configuration.

2. Using the **Configuration** drop-down list box and with the **Configuration Properties** folder selected, select the configuration for which you want to set this project's properties. If you have the **Common Properties** folder selected, the **Configuration** drop-down list box is unavailable.
3. In the left pane, select a folder and property page.
4. In the right pane, set the available properties.
5. Click **OK** to save the settings. If you want a change to take effect immediately, click **Apply**.

> **Note** Properties that are grayed are defined when the project is created; they are displayed for information only.

Properties are saved in the project's .csproj file.

For information on the **Build** menu in the Visual Studio environment, see Default and Custom Builds.

Getting Help on Properties

Documentation is available for each property; simply click the **Help** button.

File Types and File Extensions in Visual Basic and Visual C#

Project items refer to the types of files you add to a project. The project items available to you differ depending on whether you are working in a local project or a Web project. For more information, see Local vs. Web Projects and Creating Web Projects.

Adding Project Items

The Add New Item dialog box is accessed through the Project menu. For more information about adding items to your project see Adding New Project Items.

The following tables list the available project items for local and Web projects. Note that for some project items, the file extension differs depending on whether the item occurs in a Visual Basic project (indicated by .vb) or in a Visual C# project (indicated by .cs). For other project items, the file extension does not distinguish between a Visual Basic project and a Visual C# project; that is, there is only one possible file extension for the project item.

Local Project Items

Project Item	File Extension	Purpose of the Project Item
Windows Form	.vb or .cs	A form for creating Windows applications. For more information, see Creating Windows Forms.
Class	.vb or .cs	A code file that contains a class declaration. For more information, see Classes.
Module (Visual Basic only)	.vb	A file for storing groups of functions.
Component Class	.vb or .cs	A class for creating components using the visual designer. For more information, see Component Classes.
User Control	.vb or .cs	A class for creating a Windows Form control using the visual designer.
Data Form Wizard	.vb or .cs (.aspx for Web projects.)	A data form for Windows applications. For more information, see Data Form Wizard.
DataSet	.xsd	A file for creating an XML schema with **DataSet** classes. For more information, see Visual Studio Tools for Creating Datasets.
XML File	.xml	A blank XML file. For more information, see XML Designer.
XML Schema	.xsd	A file for creating a schema for XML documents. For more information, see Introduction to XML Schemas.
Code File	.vb or .cs	A blank code file.
Custom Control	.vb or .cs	A class for creating a user-drawn Windows Form control. For more information, see Authoring Controls for Windows Forms.
HTML Page	.htm	An HTML page that can include client-side code. For more information, see Design View, HTML Designer.
Inherited Form	.vb or .cs	A new form based on an existing Windows Form. For more information, see Windows Forms Inheritance.
Web Custom Control	.vb or .cs	A class for creating an ASP.NET server control. For more information, see ASP.NET Server Controls.
Inherited User Control	.vb or .cs	A new control based on an existing Windows Form control. For more information, see Inheriting from Existing Windows Forms Controls.
Windows Service	.vb or .cs	A class for creating Windows services. For more information, see Creating Windows Services.
COM Class	.vb or .cs	A class that can be exposed to COM. For more information, see COM Interoperability in Visual Basic and Visual C#.
Transactional Component	.vb or .cs	A class for use with transactional components.
Text File	.txt	An empty text file.
Frameset	.htm	An HTML file that hosts multiple HTML pages. For more information, see Introduction to Framesets.
XSLT File	.xslt	A file used to transform XML documents. For more information, see XSLT Developer's Guide.
StyleSheet	.css	A cascading style sheet used for rich HTML style definitions. For more information, see Creating an External CSS Style Sheet.
Installer Class	.vb or .cs	A class to be invoked at setup time. For more information, see Creating Installation Components.

Crystal Report	.rpt	A Crystal Report file that publishes data to a Windows form. For more information, see Crystal Report Designer Overview.
Bitmap File	.bmp	A blank bitmap image file that can be used for creating simple images.
Cursor File	.cur	A file for creating custom cursors. For more information, see Cursor Creation.
Icon File	.ico	An image file for creating a custom icon. For more information, see Icons.
Assembly Resource File	.resx	A file used to edit and define application resources. For more information, see Resources in Applications.
Assembly Information File	.vb or .cs	A file containing general assembly information. For more information, see Assemblies.
Application Configuration File	.config	A file used to configure application settings. For more information, see Configuration Files.
JScript File	.js	A script file containing JScript code. For more information, see JScript Fundamentals.
VBScript File	.vbs	A script file containing VBScript code. For more information, see VBScript User's Guide.
Windows Script Host	.wsf	A file containing script that is run as a Windows program. For more information, see Using Windows Script Files.

Web Project Items

Project Item	File Extension	Purpose of the Project Item
Web Form	Two files: .aspx and either .vb for Visual Basic or .cs for Visual C#	A form for creating Web applications. For more information, see Web Forms Pages.
Web Service	Two files: .asmx and either .vb for Visual Basic or .cs for Visual C#	A component that provides the ability to exchange interoperable messages using standard protocols such as HTTP, XML, XSD, SOAP and WSDL. For more information, see Creating XML Web Services in Managed Code.
Mobile Web Form	.aspx	A form for creating mobile Web applications. For more information, see Creating ASP.NET Mobile Web Applications.
Class	.vb or .cs	A code file that contains a class declaration.
Module (Visual Basic only)	.vb	A file for storing groups of functions.
Component Class	.vb or .cs	A class for creating components using the visual designer.
Data Form Wizard	.aspx (.vb or .cs for local projects)	A data form for Web applications. For more information, see Data Form Wizard.
DataSet	.xsd	A file for creating an XML schema with **DataSet** classes. For more information, see Visual Studio Tools for Creating Datasets.
Web User Control	.ascx	An ASP.NET server control created using the visual designer. For more information, see Developing ASP.NET Server Controls.
Mobile Web User Control	.ascx	An ASP.NET server control created using the visual designer and used in a mobile Web application. For more information, see Creating ASP.NET Mobile Web Applications.
HTML Page	.htm	An HTML page that can include client-side code. For more information, see Design View, HTML Designer.
Frameset	.htm	An HTML file that hosts multiple HTML pages. For more information, see Introduction to Framesets.
Style Sheet	.css	A cascading style sheet used for rich HTML style definitions. For more information, see Creating an External CSS Style Sheet.
XML File	.xml	A blank XML file. For more information, see XML Designer.
XML Schema	.xsd	A file for creating a schema for XML documents. For more information, see Introduction to XML Schemas.
XSLT File	.xslt	A file used to transform XML documents. For more information, see XSLT Developer's Guide.
Web Custom Control	.vb or .cs	A class for creating an ASP.NET server control. For more information, see ASP.NET Server Controls.

Code File	.vb or .cs	A blank code file.
Static Discovery File	.disco	An optional file that acts as a discovery mechanism for the XML Web service. The .disco file is not automatically created for an XML Web service. For information on creating a discovery file for your XML Web service, see Enabling Discovery for an XML Web Service.
Global Application Class	.asax	Sometimes called an asax file, this file allows you to write code to handle global ASP.NET application-level events such as **Session_OnStart** and **Application_OnStart**. The file has a name of global.asax, which you cannot change. For more information, see The Global.asax File.
Web Configuration File	.config	ASP.NET uses this file to configure the Web settings for a Web project. The file has a name of Web.config, which you cannot change. For more information, see Application Root Directory Configuration File (Web.config).
Text File	.txt	An empty text file.
Installer Class	.vb or .cs	A class to be invoked at setup time. For more information, see Creating Installation Components.
Crystal Report	.rpt	A Crystal Report file that publishes data to a Web Form. For more information, see Crystal Report Designer Overview.
Bitmap File	.bmp	A blank bitmap image file that can be used for creating simple images.
Cursor File	.cur	A file for creating custom cursors. For more information, see Cursor Creation.
Icon File	.ico	An image file for creating a custom icon. For more information, see Icons.
Assembly Resource File	.resx	A file used to edit and define application resources. For more information, see Resources in Applications.
Assembly Information File	.vb or .cs	A file containing general assembly information. For more information, see Assemblies.
JScript File	.js	A script file containing JScript code. For more information, see JScript Fundamentals.
VBScript File	.vbs	A script file containing VBScript code. For more information, see VBScript User's Guide.
Windows Script Host	.wsf	An empty code file used for Windows scripting. For more information, see Introduction to Windows Service Applications.

What's New in Projects | Visual Basic and Visual C# Projects

Visual Basic and Visual C# Projects

When you create a new project, icons in the New Project dialog box and Add Project dialog box represent the available project types and their templates. The project template that is associated with the project icon you choose determines the output type and other options available for that project.

> **Note** Some project types listed in this topic are not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

There are two basic project models in Visual Basic and Visual C#: local and Web. For more information, see Local vs. Web Projects.

The following table lists the types of projects available for Visual Basic and Visual C#.

Project Template	Used To Create
Windows Application Template	Traditional standalone Windows application or a rich front-end to a distributed Web application. For more information, see Creating Windows Applications. **Visual Basic Note** This replaces the Standard EXE project template in Visual Basic 6.0.
Class Library Template	Reusable class or component that can be shared with other projects. This project type is considered windowless and will not contain a Windows Form class. For more information, see Component Classes.
Windows Control Library Template	Custom control to use on Windows Forms. For more information, see Control Authoring for Windows Forms.
ASP.NET Web Application Template	Programmable ASP.NET Web application. For more information, see Introduction to ASP.NET Web Applications in Visual Studio.
ASP.NET Mobile Web Application Template	ASP.NET Web Application viewable on PDAs (personal digital assistants), mobile phones, and other mobile devices. For more information, see ASP.NET Mobile Designer.
ASP.NET Web Service Template	XML Web services authored with ASP.NET, functionality that can be published and called by external applications. For more information, see Creating XML Web Services in Managed Code.
Web Control Library Template	Custom control that can be used on Web Forms pages. For more information, see ASP.NET Server Controls. **Visual Basic Note** This project type is analogous to the ActiveX Control project in Visual Basic 6.0.
Console Application Template	Command-line application. For more information, see Console Application Template.
Windows Service Template	Long running applications that do not have a user interface. Windows Service Applications (formerly called "NT services") can monitor items such as system performance. For more information, see Introduction to Windows Service Applications.
New Project in Existing Folder Template	Blank project within an existing application folder for using files from a pre-existing project. This template can be used with both local and Web projects.
Empty Project Template	An empty project. The template creates the necessary file structure needed to store application information; any references, files, or components must be added manually.
Empty Web Project Template	For advanced users who want to start programming in an empty environment and add their own server-based functionality. For more information, see Web Forms Pages and Projects in Visual Studio.

See Also

What's New in Projects | File Types and File Extensions in Visual Basic and Visual C# | Creating Windows Applications | XML Web Services in Managed Code | Web Forms Pages and Projects in Visual Studio | Projects and Solutions, Environment, Options Dialog Box | Programming with Office

Class Library Template

You can use the Class Library template to quickly create reusable classes and components that can be shared with other projects. For more information about creating component classes, see Component Classes.

> **Note** The Class Library template is not available in the Standard Edition of Visual Basic .NET. For more information, see Visual Basic Standard Edition Features.
>
> **Visual Basic Note** The Class Library template replaces the ActiveX DLL project in Visual Basic 6.0. For more information, see Project Changes in Visual Basic .NET.

The template automatically adds the essential project references and files:

- AssemblyInfo - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- Class (.vb file for Visual Basic or .cs for Visual C#) - Contains the empty class module.
- References to these .NET Framework namespaces:
  - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
  - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications.
  - System.Xml - Contains classes that provide standards-based support for processing XML.

See Also

Add New Project Dialog Box | Managing Solutions, Projects, and Files | Item Management in Projects | Adding New Project Items | Component Classes

Console Application Template

The Console Application project template adds the necessary items needed to create a console application. Console applications are typically designed without a graphical user interface and are compiled into a stand-alone executable file. A console application is run from the command line with input and output information being exchanged between the command prompt and the running application. Because information can be written to and read from the console window, this makes the console application a great way to learn new programming techniques without having to be concerned with the user interface.

The template automatically adds the essential project references and files to use as a starting point for your application:

- AssemblyInfo (.vb file for Visual Basic or .cs file for Visual C#) - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- Class (.vb file for Visual Basic or .cs for Visual C#) - Contains the empty class module.
- References to these .NET Framework namespaces:
    - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
    - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications.
    - System.Xml - Contains classes that provide standards-based support for processing XML.

File Types and File Extensions in Visual Basic and Visual C# | Item Management in Projects |
Managing Solutions, Projects, and Files

Empty Project Template

The Empty Project template can be used when you want to create your own project type. The template creates the necessary file structure needed to store application information. Any references, files, or components must be added manually. For more information on adding references, see Adding and Removing References.

> **Note** This project type is not available in the Standard Edition of Visual Basic .NET. For more information, see Visual Basic Standard Edition Features.

See Also

Project Items | File Types and File Extensions in Visual Basic and Visual C# | Adding New Project Items

Empty Web Project Template

The Empty Web Project template is for advanced users who want to start with an empty project. The template creates the necessary file structure for a server-based project on your Internet Information Services (IIS) server. References and components (such as Web Forms pages) must be added manually. For information about Web projects, see Web Forms Pages and Projects in Visual Studio.

> **Note** This project type is not available in the Standard Edition of Visual Basic .NET. For more information, see Visual Basic Standard Edition Features.

Requirements

You must have:

- A computer with IIS installed.
- If you want to use FrontPage Server Extensions as your access method, the server extensions must also be installed on that computer. For more information, see Web Access Methods.
- You must have the correct Web permissions settings for your application. For more information, see Introduction to Web Application Security.

See Also

Web Walkthroughs | Project Items | File Types and File Extensions in Visual Basic and Visual C#

New Project in Existing Folder Template

The New Project in Existing Folder template creates a blank project within an existing application directory. You can then choose to add the files from the pre-existing application directory into this new project by right-clicking each of these items in Solution Explorer and selecting Include in Project on the shortcut menu.

> **Note** This project type is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

After you select this template and enter a project name, the Create a New Project in Existing Folder dialog box appears. You can type in a path or browse to an existing folder.

> **Tip** Click **Show All Files** on the Solution Explorer toolbar to view the pre-existing files.

If you create the new project for an existing Web application on a server, you can browse to an existing Web folder by selecting My Network Places in the browse window and locating the Web directory where you want to place your new project.

> **Note** To create a new Web project in an existing Web folder, you must ensure that the settings for your application are set to File Share. For more information, see Web Access Methods.

See Also

Adding New Project Items | Project Items | File Types and File Extensions in Visual Basic and Visual C#

ASP.NET Web Application Template

The ASP.NET Web Application project template is used to create an ASP.NET Web application on a computer that has Internet Information Services (IIS) version 5.0 or later installed. The template creates the basic files needed on the server to help you start designing your application. For an overview of Web applications, see Introduction to ASP.NET Web Applications in Visual Studio.

Requirements

You must have:

- A computer with IIS, version 5.0 or later, installed locally or on a remote server.
- If you want to use FrontPage Server Extensions as your access method, the server extensions must also be installed on that computer. For more information, see Web Access Methods.
- You must have the correct Web permissions settings for your application. For more information, see Web Application Security at Design Time in Visual Studio.

Files and References Added by the Template

The template automatically adds the essential project references and files to use as a starting point for your application:

- AssemblyInfo (.vb file for Visual Basic or .cs file for Visual C#) - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- Global.asax - Contains code for responding to application-level events raised by ASP.NET. For more information, see The Global.asax File.
- Styles.css - Contains default HTML style settings. For more information, see Working With CSS Styles.
- Web.config - Contains application settings for the ASP.NET application. For more information, see Application Configuration Files.
- WebForm1.aspx - Contains the portion of the default Web Forms page containing UI elements (controls), similar to an HTML page. For more information, see Web Forms Pages.
- Webform1 (.vb file for Visual Basic or .cs file for Visual C#) - Contains a class file for the default Web Forms page that contains the system-generated and user code for the page. For more information, see Web Forms Pages.
- References to these .NET Framework namespaces:
    - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
    - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications.
    - System.Drawing - Contains classes that provide access to GDI+ basic graphics functionality.
    - System.Web - Contains classes and interfaces that enable browser/server communication.
    - System.Xml - Contains classes that provide standards-based support for processing XML.

Comparison of Web Application and Web Service Templates

Both the ASP.NET Web Application and ASP.NET Web Service templates include the core references needed to create an application that accesses both Web and data technologies. The main difference between these two templates is the use for which each project type is intended. A Web application is used to create an environment with which users can visually interact through a Web browser, while an XML Web service is used to publish a service that applications can call upon to perform a task and return a value.

The primary structural difference between a Web application and a Web service is the use of ASP.NET Web Forms technology. When the ASP.NET Web Application template creates a project, it includes a Web Forms page, a Styles.css file for storing default HTML settings, and references the System.Drawing namespace. These items are the building blocks for creating interactive Web documents that users can access from a remote computer with a Web browser. For more information, see Introduction to ASP.NET Web Applications in Visual Studio.

The ASP.NET Web Service template does not provide a Web Forms page, but instead includes a service (.asmx) file. This text file serves as the addressable entry point for the XML Web service. It references code in pre-compiled assemblies, a code-behind file, or code contained in the .asmx file itself.

See Also

ASP.NET Web Service Template | Web Forms Pages and Projects in Visual Studio | Working with Web Projects | Web Walkthroughs | File Types and File Extensions in Visual Basic and Visual C# | Web Namespaces in Visual Studio

Web Control Library Template

You can use the Web Control Library project template to author custom Web server controls. The template adds the necessary project items needed to start creating a control that can then be added to any Web project. For more information, see ASP.NET Server Controls.

> **Note** This project type is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.
>
> **Visual Basic Note** This project type is analogous to the ActiveX Control project in Visual Basic 6.0. For more information, see Project Changes in Visual Basic .NET.

The template automatically adds the essential project references and files to use as a starting point for your application:

- AssemblyInfo (.vb file for Visual Basic or .cs file for Visual C#) - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- WebCustomControl file (.cs file for Visual C# or .vb file for Visual Basic) - Contains the code for your custom control, which is stored in the solution directory.
- References to these .NET Framework namespaces:
  - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
  - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications (added by default to Visual Basic projects only).
  - System.Drawing - Contains classes that provide access to GDI+ basic graphics functionality.
  - System.Management - Contains classes for managing information and events about the system, devices, and applications instrumented to the Windows Management Instrumentation (WMI) infrastructure (added by default to Visual Basic projects only).
  - System.Web - Contains classes and interfaces that enable browser/server communication.
  - System.Xml - Contains classes that provide standards-based support for processing XML (added by default to Visual Basic projects only).

ASP.NET Web Service Template

Use the ASP.NET Web Service project template to author an XML Web service that can be consumed by other Web services or applications on a network. For more information on XML Web services, see XML Web Services in Managed Code. To understand the difference between the Web service and Web application templates, see ASP.NET Web Application Template.

Requirements

You must have:

- A computer with Internet Information Services (IIS) installed.
- If you want to use FrontPage Server Extensions as your access method, the server extensions must also be installed on that computer. For more information, see Web Access Methods.
- You must have the correct Web permissions settings for your application. For more information, see Web Application Security at Run Time.

Files and References Added by the Template

The template automatically adds the essential project references and files to use as a starting point for your application:

- AssemblyInfo (.vb file for Visual Basic or .cs file for Visual C#) - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- Global.asax – Contains code for responding to application-level events raised by ASP.NET. For more information, see The Global.asax File.
- Service file (.vb file for Visual Basic or .cs file for Visual C#) – Contains the class that is used to add functionality to your XML Web service. For more information, see Creating and Accessing XML Web Services Walkthroughs.
- Web.config – Contains a file with application-specific settings. For more information, see Application Configuration Files.
- References to these .NET Framework namespaces:
    - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
    - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications.
    - System.Web - Contains classes and interfaces that enable browser/server communication.
    - System.Web.Services - Contains classes that enable you to build and use XML Web services, programmable entities residing on a Web server and exposed via standard Internet protocols.
    - System.Xml - Contains classes that provide standards-based support for processing XML.

Windows Application Template

The Windows Application project template in Visual Basic and Visual C# lays the groundwork for a standard Windows application. For more information on creating a Windows application, see Creating a Windows Application Project.

> **Visual Basic Note** This application replaces the Standard EXE application in Visual Basic 6.0. For more information, see Project Changes in Visual Basic .NET.

The template automatically adds the essential project references and files to use as a starting point for your application:

- AssemblyInfo - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- Form (.vb file for Visual Basic or .cs for Visual C#) - Contains the Windows Form.
- References to these .NET Framework namespaces:
  - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
  - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications.
  - System.Drawing - Contains classes that provide access to GDI+ basic graphics functionality.
  - System.Windows.Forms - Contains classes for creating Windows-based applications that take full advantage of the rich user interface features available in the Microsoft Windows operating system.
  - System.Xml - Contains classes that provide standards-based support for processing XML.

Windows Control Library Template

The Windows Control Library project template is used to create custom controls to use on Windows Forms. For more information , see Windows Forms Controls.

> **Note** This project type is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.
>
> **Visual Basic Note** This template is analogous to the User Control project in Visual Basic 6.0. For more information, see Project Changes in Visual Basic .NET.

The template automatically adds the essential project references and files to use as a starting point for your application:

- AssemblyInfo (.vb file for Visual Basic or .cs file for Visual C#) - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- UserControl file (.cs file for Visual C# or .vb file for Visual Basic) - Contains a class that derives from **System.Windows.Forms.UserControl** and implements a user control.
- References to these .NET Framework namespaces:
  - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
  - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications.
  - System.Drawing - Contains classes that provide access to GDI+ basic graphics functionality.
  - System.Windows.Forms - Contains classes for creating Windows-based applications that take full advantage of the rich user interface features available in the Microsoft Windows operating system.
  - System.Xml - Contains classes that provide standards-based support for processing XML.

Windows Service Template

The Windows Service template adds the necessary items needed to create a Windows Service application, a long-running executable application that runs in its own Windows session. For more information, see Introduction to Windows Service Applications.

> **Note** This project type is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

The template automatically adds the essential project references and files to use as a starting point for your application:

- AssemblyInfo (.vb file for Visual Basic or .cs file for Visual C#) - Used to describe the assembly and specify versioning information. For more information, see Programming with Assemblies.
- Service file (.cs file for Visual C# or .vb file for Visual Basic) - Contains the designer file, which is stored in the solution directory.
- References to these .NET Framework namespaces:
  - System - Contains fundamental classes and base classes that define commonly used values and reference data types, events and event handlers, interfaces, attributes, and processing exceptions.
  - System.Data - Contains classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications.
  - System.ServiceProcess - Contains classes that allow you to install and run services, which are long-running executables with no user interface.
  - System.Xml - Contains classes that provide standards-based support for processing XML.

Referencing Namespaces and Components

Project references are used to access the properties, methods, and events of a defined object and apply them to your programming. The following topics contain an overview of references in Visual Basic and Visual C# and give instructions on how to add, remove, and manage existing references.

In This Section

Project References
Describes the basic concepts of project references.
Adding and Removing References
Explains how to add and remove references to assemblies, components, and other projects in the same solution.
Troubleshooting Broken References
Describes the main causes of broken references and ways to fix them.
Managing Project Web References
Describes the procedure used to rename or update a project Web reference.

Related Sections

Adding and Removing Web References
Describes how to add a Web reference using the Project menu or Server Explorer.
Introduction to the .NET Framework Class Library in Visual Studio
Describes the .NET class library.

Project References

In order to write code against an external component, your project must first contain a reference to it. A reference can be made to the following types of components:

- .NET class libraries or assemblies
- COM components
- Other class libraries of projects in the same solution
- XML Web services

For more information about XML Web service references, see Web References.

> **Visual Basic Note** Project references are managed differently in Visual Studio .NET than they were in Visual Basic 6.0. For more information, see Project Changes in Visual Basic .NET.

References to Shared Components

At run time, components must be in one of two locations: in the output path of the project or the global assembly cache (see Global Assembly Cache). If the project contains a reference to an object that is not in one of these locations, the reference must be copied to the output path of the project when the project is built. The CopyLocal property indicates whether this copy needs to be made. If the value is **true**, the reference is copied. If **false**, the reference is not copied.

By default, the **CopyLocal** property is set to **false** if the assembly or component is in the global assembly cache or is a framework component. Otherwise, the value is set to **true**. Project-to-project references are always set to **true**.

Project-to-Project References

In a solution with multiple projects, you can create references to objects authored in another project that resides in the same solution. This creates an interdependency that requires special consideration when building and running the application. For more information, see Preparing and Managing Builds.

See Also

Reference Path, Common Properties, <Projectname> Property Pages Dialog Box | Adding and Removing References | Troubleshooting Broken References | Referencing Namespaces and Components | Programming with Assemblies

Adding and Removing References

In order to use a component in your application, you must first add a reference to it. Visual Studio .NET provides three options on the Add Reference dialog box:

- .NET - Lists all .NET Framework components available for referencing.
- COM - Lists all COM components available for referencing.
- Projects - Lists all reusable components created in local projects.

You can also add Web references in the Add Web Reference dialog box. For more information, see Adding and Removing Web References.

> **Note** You should avoid adding file references to outputs of another project in the same solution, because doing so may cause compilation errors. Instead, use the Projects tab of the Add References dialog box to create project-to-project references. This makes team development easier, by allowing for better management of the class libraries you create in your projects. For more information, see Troubleshooting Broken References.

To add a reference

1. In Solution Explorer, expand the project node you want to add a reference to.
2. Right-click the **References** node for the project and select **Add Reference** from the shortcut menu.
3. To add a reference to a component or components, do the following:
   a. In the **Add Reference** dialog box, select the tab indicating the type of component you want to reference. For more information, see Add Reference Dialog Box.
   b. In the top pane, select the component you want to reference, and then click the **Select** button.

      > **Tip** If the component you are looking for is not in the list, you may locate it using the **Browse** button.

      The component you referenced appears in the **SelectedComponents** pane of the dialog box. Repeat Step b for each additional component you wish to add.

   c. Click **OK** when you have added references to all the components you need.

      Selected references will appear under the **References** node of the project.

To remove a reference

- In Solution Explorer, right-click the reference in the **References** node, and select **Remove** from the shortcut menu.

By default, the Add References dialog box only lists assemblies that are in the Public Assemblies folder (Program Files\Microsoft Visual Studio .NET\Common7\IDE\Public Assemblies) or in the Global Assembly cache. You can add your own assemblies to the list by adding a registry key to specify their location.

To add assemblies to the Add References dialog box

1. In Windows, click the **Start** button, click **Run**, then type **regedit** to open the Registry Editor.
2. Select the registry key **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\VisualStudio\7.0\AssemblyFolders**
3. On the **Edit** menu, point to **New**, then click **Key**.
4. Enter a name for the key (for example, **MyAssemblies**).
5. Select the **(Default)** value for the key that you just added.
6. On the **Edit** menu, choose **Modify**.
7. In the **Edit String** dialog box, select the **Value data** field and enter the full path to the folder where your assemblies are located.

   > **Note** Only the specified folder will be searched each time the Add References dialog box is opened; subfolders will not be searched. You must add a separate key for each subdirectory to be searched.

Troubleshooting Broken References

If your application attempts to use a broken reference, an exception error is generated. The inability to find the referenced component is the primary trigger for the error, but there are several situations in which a reference can be considered broken. These instances are shown in the following list:

- The project's reference path is incorrect or incomplete.
- The file being referenced has been deleted.
- The file being referenced has been renamed.
- The network connection or authentication has failed.
- The reference is to a COM component that is not installed on the computer.

The following are remedies to these problems.

> **Note** Files in assemblies are referenced with absolute paths in the project file. Because of this, it is possible for users working in a multideveloper environment to be missing a referenced assembly in their local environment. To avoid these errors, it is better in these cases to add project-to-project references. For more information, see Adding and Removing References and Programming with Assemblies.

Reference Path Is Incorrect

If projects are shared on different computers, some references might not be found when a component is located in a different directory on each computer. References are stored under the name of the component file (for example, MyComponent). When a reference is added to a project, the folder location of the component file (for example, C:\MyComponents\) is appended to the Reference Path project property.

When the project is opened, it attempts to locate these referenced component files by looking in the directories on the reference path. If the project is opened on a computer that stores the component in a different directory, such as D:\MyComponents\, the reference cannot be found and an error appears in the Task List.

To fix this problem, you can delete the broken reference and then replace it using the Add Reference dialog box. Another solution is to use the Reference Path item in the project's property pages and modify the folders in the list to point to the correct locations. The Reference Path property is persisted for each user on each computer, so modifying your reference path does not affect other users of the project.

> **Tip** Project-to-project references do not have these problems. For this reason, use them instead of file references, if possible. For more information, see Components and Assemblies.

To fix a broken project reference by correcting the reference path

1. In Solution Explorer, right-click your project node and choose **Properties** from the shortcut menu.
2. Select the appropriate property page in the dialog box.

   - If you are using Visual Basic, select **Reference Path** under the **Common Properties** folder in the left pane. In the **Reference Path** pane, type the path in the **Folder** field, and then click the **Add Folder** button.

     -or-

   - If you are using Visual C#, select **References Path** under the **Common Properties** folder in the left pane. Click in the large edit box to get an edit point, and then type the path to the folder that contains the item you want to reference and click **OK**.

Referenced File Has Been Deleted

It is possible that the file being referenced has been deleted and no longer exists on the drive.

To fix a broken project reference for a file that no longer exists on your drive

- Delete the reference. For more information, see Adding and Removing References.
- If the reference exists in another location on your computer, read it from that location. For more information, see Adding and Removing References.

Referenced File Has Been Renamed

It is possible that the file being referenced has been renamed.

To fix a broken reference for a file that has been renamed

- Delete the reference, and then add a reference to the renamed file.

  > **Tip** If the reference exists in another location on your computer, you need to read it in from that location. For more information, see Adding and Removing References.

Network Connection or Authentication Has Failed

There can be a variety of causes for inaccessible files: a failed network connection or a failed authentication, for example. Each cause might have a unique means of recovery; for example, you might need to contact your local administrator for access to the required resources. However, deleting the reference and fixing the code which used it is always an option. For more information, see Adding and Removing References.

COM Component Is Not Installed on Computer

If a user has added a reference to a COM component and a second user attempts to run the code on a computer that does not have this component installed, the second user will receive an error that the reference is broken. Installing the component on the second computer will correct the error. For more information about using references to COM components in your projects see COM Interoperability in Visual Basic and Visual C#.

Managing Project Web References

Web references differ from traditional references and components in that they refer to XML Web services published on either a local intranet or the Internet. The standard references that programmers are accustomed to adding to their applications are to components and class libraries installed on the local computer. You add a Web reference to your project when you want to incorporate functionality from a Web service into your application. For instructions on creating a Web reference, see Adding and Removing Web References.

You manage project Web references by renaming or modifying them to suit your needs or by updating them when changes have been made to the Web service the reference calls.

Renaming a Project Web Reference

The Web reference's name is also its programmatic namespace. The namespace can be changed to suit your needs. You can change the name of the Web reference to any string expression that is meaningful to its function. For example, you could change the name of a Web reference that handles account totals to "AccountTotal."

To rename a Web reference in a project

1. In Solution Explorer, expand your project's **Web References** folder, and then select the node for the reference you want to rename.
2. On the **File** menu, choose **Rename**.

   A box appears around the selected reference.

3. Type the new name for the reference, and press **ENTER**.

   Note If you have used the old name elsewhere in your project code, remember to change each occurrence to the new name.

Updating a Project Web Reference

If your application contains a Web reference to an XML Web service that has been recently modified on the server, you may need to update the reference in your project. For example, you may need to update a Web reference when new methods are added to an existing XML Web service on a server. In this case, you would need to generate a new proxy for the Web service so you can access the new method; this happens automatically when you update the Web reference.

To update a project Web reference

1. In Solution Explorer, access your project's **Web References** folder and select the node for the Web reference you want to update.
2. Right-click the reference and click **Update Web Reference**.

   The new files for the XML Web service are downloaded to your project. Information for the XML Web service is updated within your project.

URL Behavior Property

Each Web reference in your project interacts with a proxy class that is used to access the Web service's contents. You can use the UrlBehavior property to control the way a proxy class obtains the URL for a specific Web reference. The property has two settings:

Setting	Effect
Static	The proxy class sets the URL using a hard-coded URL when you created the instance of the class.
Dynamic	The application obtains the URL at run time from the <appSettings> Element element of your application's configuration file.

For more information on dynamic versus static Web references, see Locating XML Web Services.

Working with Web Projects

ASP.NET Web applications and XML Web services allow you to create applications that leverage the power of the World Wide Web. These types of projects run on a Web server, sending and receiving information using standard protocols such as HTTP and XML. Using Web projects, you can create everything from a traditional Web site that serves HTML pages, to fully featured business applications that run on an intranet or the Internet, to sophisticated business-to-business applications.

Introduction to Web Projects

There are many types of projects available in Visual Studio .NET, each designed for a specific purpose. Each project contains specific types of files, references, and default items. In Visual Basic and Visual C#, two of the major kinds of projects you can create are Web-based projects and local projects. Web projects are stored and managed on a Web server with the purpose of being exposed to a network, whereas local projects are stored locally and not optimized for network access.

Visual Basic and Visual C# include templates to help you create three types of Web-based projects:

- ASP.NET Web Application template - a programmable Web application with designer support for creating Web Forms pages and incorporating features of ASP.NET.
- ASP.NET Web Service template - an application that provides the ability to exchange interoperable messages across the Web using standard protocols such as HTTP, XML, XSD, SOAP, and WSDL.
- Empty Web Project template - an empty Web application you can customize.

> **Note** There is also a Web Control Library template, but it is actually a local project.
>
> **Note** The Empty Web Project and Web Control Library templates are not available in the Standard Edition of Visual Basic .NET; the Web Control Library template is not available in the Standard Edition of Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

For more information about Web projects, see Working with Web Projects. For more information about choosing between Web and local projects, see Windows Forms and Web Forms Recommendations and Local vs. Web Projects.

Web Project User Interface

When you create a Web application in Visual Basic and Visual C#, you create programmable Web pages that serve as the user interface for your Web application. A Web Forms page presents information to the user in any browser or client device and implements application logic using server-side code. Web Forms page output may contain almost any HTTP-capable language, including HTML, XML, WML, and ECMAScript (JScript, JavaScript). For more information, see Introduction to Web Forms Pages.

Access and Storage for Web Project Files

You can choose two ways for Visual Studio to manage the files in your ASP.NET Web application:

- **FrontPage Server Extensions access** - All files are managed using the HTTP protocol.
- **File-share access** - All files are managed using Windows-based file management commands. This option requires LAN access to the server, but it can be slightly faster because there is less management overhead. In addition, file-share access provides superior support for source-code control.

For more information on access methods and choosing the correct method, see Web Access Methods.

In addition, Visual Studio keeps files in a cache on the local computer. The local directory is created and used for two reasons:

- Certain designers require file-level write access to some of your project files. If you are using FrontPage Server Extensions, you access the server using HTTP, which would preclude these designers from accessing the files they need.
- Keeping files in the cache allows you to work on your Web Forms pages in Offline mode. For more information, see Taking Web Projects Offline.

The cache is always kept in sync with the actual project files on the server. (If you are in Offline mode, the files are synchronized when you reconnect to the server project.) When you change a file in your project, the update is written to both the server and the cache. In a few instances, files are kept in the cache but not written to the server, as with intermediate files created during a build process.

Essentially, the cache is a temporary directory used by Visual Studio. You will see references to the cache when you are creating a deployment project. However, you should not otherwise have any cause to see or work with the cache.

Web Project Security

On the file level, you can use the Web permissions feature of Visual Studio to control who can gain access to your Web project files and what level of access individuals have to the application. The permissions you set in Visual Studio are applied to Windows entities (folders, users, groups, and so on.) They are similar to equivalent permissions you can set in Internet Information Services (IIS). You can choose to set individual rights or simply inherit the rights of the Web folder that the application is stored in. For more information, see Setting Web Permissions.

On an application level, security concerns are a critical part of the decisions you must make in designing and creating your Web application. Web applications by definition allow users access to a central resource — the Web server — and through it, to others such as database servers. By understanding and implementing proper security measures, you guard your own resources as well as provide a secure environment in which your users are comfortable working with your application. For more information on the security considerations you must face when creating your application, see Introduction to Web Application Security.

Debugging and Deploying Web Projects

When you build a Web project, the application files are remotely compiled on the Web server. Information is sent to the Web application, processed, and the results are then returned to the client computer and viewed as a Web Form or an update of information on a Web Form. For more information, see Debugging Preparation: ASP.NET Web Applications.

You can use deployment projects to quickly and easily deploy your Web applications to the appropriate servers. For more information, see Walkthrough: Deploying a Web Solution.

Web Access Methods

You can choose two ways for Visual Studio to manage the files in your ASP.NET Web application:

- **FrontPage Server Extensions access** - All files are managed using the HTTP protocol.
- **File-share access** - All files are managed using Windows-based file management commands. This option requires LAN access to the server, but it can be slightly faster because there is less management overhead. In addition, file-share access provides superior support for source-code control.

> **Note** If you create your Web application using FrontPage access on a server with a FAT or FAT32 partition, you will not be able to use source control. This is because the FAT partition does not allow for full security functionality, so all operations are performed in the context of the same guest account. All source control operations are performed in the context of this anonymous user (IUSR_Machinename). This can incorrectly cause your files to appear to be exclusively checked out to another user when you attempt to perform check-in or check-out operations. To resolve this problem, convert your FAT partition to NTFS file system.

Choosing the Best Access Method

There are two primary items to consider when choosing the appropriate Web access method. First, you need to consider the location of the server you plan to use. File share requires that you have sufficient access rights on the server to create a file structure. If you do not have access to a shared folder on the Web server, you cannot use the file share access method. For this reason, file share is more appropriate for creating applications on the local intranet. FrontPage Server Extensions are a better choice for developing projects on the Internet, because they use reference pointers to the server.

Second, you need to consider the source control model you prefer to use. When you create a Web project with FrontPage as the access method, only one copy of the Web project exists and all developers work in this single project. Each developer checks out a file exclusively, meaning that only one developer can edit a file at a time. In addition, developers can only access the project using FrontPage Server Extensions.

> **Note** Using FrontPage Server Extensions as your access method is not recommended for a multiuser development environment.

A project using the file share access method behaves similarly to local projects under source control. Developers check out copies of the project files from source control and then check their changes back into the same source control system.

When to Specify the Web Access Method

The default access method for Web projects is file share. However, before you create a new Web project, you can set the preferred Web access method in the Web Settings page of the Project node in the Options dialog box. For more information on creating a new Web project, see Creating Web Projects.

After a Web project is created, the Web access method is stored and used the next time the project is opened. If there is a problem, you can switch access methods by using the Web Access Failed dialog box. For more details on the information in this dialog box see Web Access Failed Dialog Box.

You can change a Web project's access method in the Project Property Pages dialog box as long as the Web project is not under source control. Visual Studio will use the new access method the next time the Web project is opened. For more information about choosing a different access method, see Changing Web Project Access Methods.

See Also

Changing Web Project Access Methods | Web Access Failed Dialog Box | Compilation and Deployment of Web Projects | Creating Web Projects | Opening Web Projects | Managing Project Web References | Visual Basic and Visual C# Projects

Changing Web Project Access Methods

Web applications can access files on a network by using either file share or FrontPage Server Extensions access methods. For more information about which Web access method to use, see "Choosing the Best Access Method" in Web Access Methods. You can change the Web Access method for a Visual Basic project, but the change will not take effect until the next time the project is opened.

For more information about changing the default Web access method, see Creating Web Projects.

> **Note** If you change the Web access method to file share, you must specify a valid path to your Web project. A fully qualified path to your Web folder must be added in the Web Settings page of the Project Properties dialog box.

To change an existing Web project's access method

1. In Solution Explorer, right-click the project node, then choose **Properties** from the shortcut menu.
2. In the **Common Properties** folder in the left pane, click **Web Settings**.
   - Choose either **File share** or **FrontPage** from the **Web Access Method** section.
3. Close your project and reload it.

See Also

Web Access Methods | Web Settings, Common Properties, <Projectname> Property Pages Dialog Box (C#) | Web Settings, Common Properties, <Projectname> Property Pages Dialog Box (Visual Basic) | Visual Basic and Visual C# Projects | Project Type Changes in Visual Basic .NET | Web Projects | Creating Web Projects | Working with Web Projects | Opening Web Projects

Creating Web Projects

A Web project can be either a standard ASP.NET Web application or an XML Web service that is designed to be consumed by other applications. For more information, see Creating Web Applications and Services.

The Web server on which your project exists can be on either a local or remote computer. When you create a new Web project, you must specify the type of file access to use; Visual Studio .NET uses file-share Web access as the default for all your Web projects, unless you change the default setting in the Options dialog box. To determine which Web access method to use, see "Choosing the Best Access Method" in Web Access Methods. If you want to change the Web access method, see Changing Web Project Access Methods.

> **Note** Changing the default Web access method in the Options dialog box does not affect a project you have open; the setting affects only future Web projects. Therefore, you should usually specify a Web access method before you create a new Web project.

To specify the default Web access method

1. On the **Tools** menu, choose **Options**.
2. Expand the **Projects** node in the left pane, and then select **Web Settings**.
3. In the **Preferred Access Method** section, choose either the **File share** or **FrontPage** access method.

   All new Web projects you create will use that Web access method as the default. If you want to change the Web access method for an existing Web project, see Changing Web Project Access Methods.

To create a new Web project

1. On the **File** menu, point to **New** and then click **Project** to display the **New Project** dialog box.
2. In the **Project Types** pane, select either **Visual Basic** or **Visual C#**.
3. In the **Templates** pane, select the type of Web project you want to create. For an overview of Web project types, see Visual Basic and Visual C# Projects.

   - **ASP.NET Web application** - For more information, see Introduction to Web Forms Pages.

     - or -

   - **ASP.NET Web Service** - For more information, see Introduction to Programming XML Web Services in Managed Code.

     - or -

   - **Empty Web Project** - For more information, see Empty Web Project Template.

     > **Note** The Empty Web project type is not available in the Standard Edition of Visual Basic .NET. For more information, see Visual Basic Standard Edition Features.

4. In the **Location** text box, specify the URL where you want to place the Web project, including the name you want to give it.

   For example, to create a project titled myWebApp at the default localhost location, the URL string placed in the Location text box will look like this:

   ```
   http://localhost/myWebApp
   ```

   This allows for exact placement of your project files in a specific directory on a Web server.

   > **Note** If the local computer you are working on is also a Web server, you can create your Web project on that computer. The first time you start Visual Studio, the default location of a Web project is your local computer. In subsequent Visual Studio sessions, you can select the location of a previously used Web server from a drop-down list. If you want to choose a different server, you can click the **Browse** button to find other servers on your network, or you can type in the URL to a server (for example, http://domain.com) and press ENTER.

5. Click **OK** to create the Web project.

   Visual Studio connects to the server and adds the appropriate project items to Solution Explorer in the project node.

Opening Web Projects

The method you use to open a Web project depends on the source-control options you have chosen for the project. If you are using source control to manage your project files, you must open and save project files according to the guidelines set in the Source Control node of the Options dialog box. For more information on using source control to manage your project files, see Source Control Services.

For Web projects that are not under source control, project files stored on a server can be opened simultaneously by multiple users. When the project is opened, copies of the project files are stored on your local computer. Before executing a build command, Visual Studio replaces the project files stored on the server with the edited files located in your local directory. If you execute the Build command either directly or when debugging your project, and there is another developer currently working on the project, you will overwrite any project files saved by the second developer.

When you open a Web project, the system opens it using the Web access method (file share or FrontPage Server Extensions) last used for the project. For more information about choosing a Web access method, see Web Access Methods.

To open an existing Web project that is not part of source control

1. On the **File** menu, point to **Open**, and then choose **Project From Web**.
2. In the **Open Project From Web** dialog box, enter the URL of the Web server where the project is located, and then click **OK**.
3. In the **Open Project** dialog box, double-click your Web project's folder.
4. Double-click the appropriate project file to open the project.

   The Web project opens and its files are listed in Solution Explorer. If the project could not be opened, an error message is shown that allows you to try another Web access method or to work offline. For more information, see Troubleshooting Web Projects.

Setting Web Permissions

Using the Web permissions facilities of Visual Studio, you can control who can gain access to your Web project files and what level of access individuals have to the application. The permissions you set in Visual Studio are applied to Windows entities (folders, users, groups, and so on.) They are similar to equivalent permissions you can set in Internet Information Services (IIS). You can choose to set individual rights or simply inherit the rights of the Web folder that the application is stored in. For more information, see the topics on permissions in the IIS documentation (http://www.microsoft.com/windows2000/en/server/iis/).

To inherit the rights for a Web project

1. From the **Project** menu, click **Web Projects**, and then select **Web Permissions** to open the **Web Permissions** dialog box.

   Note You can use the Web permissions facility of Visual Studio only if the Web access method of your project is FrontPage Server Extensions. For more information, see Web Access Methods.

2. In the **Settings** tab, select **Use same permissions as the root Web server**.

To set individual rights for a Web project

1. From the **Project** menu, click **Web Projects**, and then select **Web Permissions** to open the **Web Permissions** dialog box.

   Note You can use the Web permissions facility of Visual Studio only if the Web access method of your project is FrontPage Server Extensions. For more information, see Web Access Methods.

2. Add and set your user's access by doing the following:
   a. In the **Users** tab, click the **Add** button to add new users to the list.
   b. Select the user you added and click the **Edit** button to open the **Edit Users** dialog box.
   c. Select the appropriate user access rights, and then click **OK**.
   d. In the **Groups** tab, click **Add** to add a user group to the list.
   e. Repeat for each user you want to add.
3. Set the computer rights necessary as follows:
4. In the **Computers** tab, click **Add** to add a new computer.
   a. In the **Add Computer** dialog box, type in the IP address for the desired computer, select the required access level, and then click **OK**.
   b. Repeat for each computer you want to add to the list.

Setting Unique Permissions for an ASP.NET Web Application

When you set up access rights to your ASP.NET Web application, you have a choice between inheriting the permissions set on the default Web root where your application exists, or setting individual rights for users, groups, and computers. For more information, see Setting Web Permissions.

> **Note** You can use the Web permissions facility of Visual Studio only if the Web access of your project is FrontPage Server Extensions. For more information, see Web Access Methods.

To set unique permissions for a Web application

1. In Solution Explorer, select the project you want to set permissions for.
2. On the **Projects** menu, click **Web Project** and then **Web Permissions**.

   > **Note** Your project must use Front Page Server Extensions in order for this item to be available.

3. On the **Settings** tab, select **Use unique permissions for this Web application**.

   This option specifies that the current Web application does not inherit its permissions setting from the root Web application.

4. Choose **Apply**.

   > **Note** You must apply the change to unique settings in this tab before the other tabs are available for changes.

5. Set the appropriate rights:

   - To set rights for individual users, click the **Users** tab. For more information, see Manipulating User Permissions for ASP.NET Web Applications.
   - To set rights for groups of users, click the **Groups** tab. For more information, see Manipulating Group Permissions for ASP.NET Web Applications.
   - To set rights for computers by IP address, click the **Computers** tab. For more information, see Manipulating Computer Permissions to ASP.NET Web Applications.

Manipulating Computer Permissions to ASP.NET Web Applications

You can use the Web Permissions dialog box to manipulate computer permissions to your ASP.NET Web applications in a variety of ways:

- You can add the names of computers you want to have access to your application and set their permission levels.
- You can modify permission levels for a computer.
- You can remove a computer's permissions to your applications.

> **Note** You can use the Web permissions facility of Visual Studio only if the Web access of your project is FrontPage Server Extensions. For more information, see Web Access Methods.

To add a computer to a Web application

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. On the **Settings** tab, select **Use unique permissions for this Web application** and then click **Apply**.
3. On the **Computers** tab, click **Add**.
4. In the **IP Address** boxes, type the address for the computer.

   > **Note** You can specify a group of computers that have the same initial address by using an asterisk (*).

5. In the **Computer permissions** box, select the permission level for the computer.
6. Click **Apply**.

Once a computer has been given permissions, you can change the permissions of the computers.

To change permissions for a computer

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. On the **Computers** tab, select the computer or computer mask to edit, and click **Edit**.
3. In the **Edit Computer** dialog box, select the new level of permission for the group.
4. Click **Apply**.

Computers Tab, Web Permissions Dialog Box

Manipulating User Permissions for ASP.NET Web Applications

You can use the Web Permissions dialog box to manipulate user permissions to your ASP.NET Web applications in a variety of ways:

- You can add the names of users you want to have access to your application and set their permission levels.
- You can modify permission levels for a user.
- You can remove a user's permissions to your applications.

> **Note** You can use the Web permissions facility of Visual Studio only if the Web access of your project is FrontPage Server Extensions. For more information, see Web Access Methods.

To add users to a Web application

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. On the **Settings** tab, select **Use unique permissions for this Web application** and then click **Apply**.
3. On the **Users** tab, click **Add** and specify the user to add:

   - In the **Add Names** box, type the domain and user name for the new user in this format: *domain**username*.

   –or–

   - In the **Obtain list from** box, select the domain and add users from the **Names** field.

4. In the **New users can** box, select the permission level of the new users. Note that the selected permission level applies to all new users in the **Add Names** field.
5. Choose **Apply**.

You can change the permissions for each user.

To change permissions for a user

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. On the **Users** tab, select the user to edit and click **Edit**.
3. In the **Edit Users** box, select the new level of permission for the user.
4. Choose **Apply**.

You can revoke the permissions that an individual has by deleting an item from the user list.

To delete user permissions on a Web application

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. Select the user to remove from the **Users** tab.

   > **Note** If your master Web server is on an operating system using the file allocation table (FAT) file system instead of the NTFS file system, you cannot change the permissions for groups.

3. Click **Remove**.
4. Click **Apply**.

Manipulating Group Permissions for ASP.NET Web Applications

You can use the Web Permissions dialog box to manipulate user permissions to your ASP.NET Web applications in a variety of ways:

- You can add the names of groups you want to have access to your application and set their permission levels.
- You can modify permission levels for a group.
- You can remove a group's permissions to your applications.

> **Note** You can use the Web permissions facility of Visual Studio only if the Web access of your project is FrontPage Server Extensions. For more information, see Web Access Methods.

To add groups of users to a Web application

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. On the **Settings** tab, select **Use unique permissions for this Web application** and then click **Apply**.
3. On the **Groups** tab, click **Add**.
4. In the **Add Names** box, type the domain and group name for the new groups in this format: *domain\group name*.

   –or–

   In the **Obtain list from** box, select the domain and add groups from the **Names** field.
5. In the **New users can** box, select the permission level of the new groups. Note that the selected permission level applies to all new groups in the **Add Names** field.
6. Choose **Apply**.

Once a group has been given permissions, you can change the permissions of the group.

To change permissions for a group

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. On the **Groups** tab select the group to edit, and click **Edit**.
3. In the **Edit Groups** dialog box, select the new level of permission for the group.
4. Choose **Apply**.

You can revoke the permissions that a group has by deleting the group from the group list.

To delete group permissions on a Web application

1. On the **Projects** menu, point to **Web Project**, and then click **Web Permissions**.
2. Select the group to remove from the **Group** tab.

   > **Note** If your master Web server is on an operating system using the file allocation table (FAT) file system instead of the NTFS file system, you cannot change the permissions for groups.

3. Click **Remove**.
4. Click **Apply**.

Taking Web Projects Offline

Visual Studio gives you the ability to make changes to your Web application while working away from your network. This feature is useful when you need to make source code changes at times when you do not have access to your network. For example, you may need to make changes while traveling with a laptop. If you need to work on your project while offline, you can run and debug your Web project without having a network connection.

> **Note** Any Web references in your application that point to procedures on external computers will not be accessible offline. Procedures using these references will throw exception errors.

When your connection is restored, you can synchronize your folders. Visual Studio compares your local application files with the files stored on the server. If Visual Studio finds differences between the two sets of files, it will prompt you to correct the differences. The synchronization process is bidirectional, meaning that changes reflected on server files can be incorporated to your local directory.

Another consideration when working offline is the source-control options you have chosen for your project files. These options have a direct effect on the way you access and save changes to your source files. For more information, see Source Control Services.

To take a Web project offline

- From the **Project** menu, click **Web Project**, and then select **Work Offline**.

  Visual Studio updates the files stored in the local Web cache directory by replacing them with the current files located on the server.

  > **Note** The location of the local Web cache is specified in the **Web Options** dialog box. For more information about Web options, see Web Settings, Projects, Options Dialog Box.

To synchronize all Web project files

- From the **Project** menu, click **Web Project**, and then select **Synchronize All Folders**.

To examine possible differences between online and offline Web project files

- From the **Project** menu, click **Web Project**, and then select **Compare to Master Web**. ("Master Web" means the files on the server.)

Refreshing Web Project Files

Note the difference between refreshing and synchronizing. Refreshing files makes the Web project files located on your computer (the local files) identical to the files on the server by copying files to the local computer or removing files that do not exist on the server. Synchronizing compares local and server files and updates both sets of files with changes found during the comparison.

To refresh Web project files

- Click the **Refresh** button on the Solution Explorer toolbar.

Resource File Naming Conventions

This section describes the naming convention for assembly manifest resources in Visual Basic and Visual C# projects.

In This Section

XML Resources
Covers those files whose extension is .resx and whose **BuildAction** property is set to **Embedded Resource**.

Non-XML Resources
Covers any file whose **BuildAction** property is **EmbeddedResource** and whose extension is something other than .resx.

Related Sections

Managing Projects
Provides links to topics about Visual Basic and Visual C# projects.

XML Resources

An XML resource file is a file whose extension is .resx and whose **BuildAction** property is set to **Embedded Resource**. Such XML files must follow a specific schema understood by the ResXToResources conversion tool. With this tool, XML resource files are transformed into binary large objects (BLOBs) prior to inclusion in the assembly manifest.

The following is the file naming convention for such resources:

base_filename[**.***optional RFC 1766 culture info string*]**.resx**

Aside from file system limitations, there are no restrictions on *base_filename* or the optional *RFC 1766 culture info string*. Examples of valid XML resource file names include:

- MyResource.resx
- MyResource.de-de.resx
- My.Resource.File.resx

See Also

Non-dependent XML Resource Files | Dependent XML Resource Files | File Properties

Non-dependent XML Resource Files

A non-dependent XML resource file is defined as a .resx file whose parent object in the hierarchy is either a folder or the project root. The manifest resource name of this resource is computed as follows: the default namespace of the folder containing the XML resource file + the name of the XML resource file + **.resources**. For example, consider a project named Project1 with root namespace RootNamespace and the following hierarchy: Project1->Folder1->MyResource.de-de.resx.

For Visual Basic, where the default namespace for every folder is always the root namespace, the name `MyResource.resx` would be transformed to the manifest resource name `RootNamespace.MyResource.de-de.resources`.

For Visual C#, where the default namespace for every folder is always inferred from the folder's location in the hierarchy, the name MyResource.resx would be transformed to the manifest resource name `RootNamespace.Folder1.MyResource.de-de.resources`.

Dependent XML Resource Files

Dependent XML Resource Files

A dependent XML resource file is a file whose parent is another file.

In This Section

XML Resources Dependent Upon Invalid Code Files
Briefly describes the resource-naming scheme for this type of resource.
XML Resources Dependent Upon Valid Code Files
Briefly describes the resource-naming scheme for this type of resource.

Related Sections

XML Resources
Describes an XML resource file and the naming convention for such files.

XML Resources Dependent Upon Invalid Code Files

If an XML resource file is dependent upon a file for which a valid code model cannot be obtained, then the project system will follow the resource-naming scheme described in Non-dependent XML Resource Files.

See Also

XML Resources Dependent Upon Valid Code Files

XML Resources Dependent Upon Valid Code Files

If an XML file is dependent upon a valid language code file for the given project, and if a file code-model object can be obtained on the said file, then the manifest-resource name of the XML resource file shall be computed as follows: full name of the first class in the file that is the parent of the resource file + optional RFC 1766 culture info string (if supported by .NET Framework Resource Manager) + **.resources**.

If the parent of the XML resource file does not contain any class definitions, then the project system will fall back to the resource-naming scheme described in Non-dependent XML Resource Files.

For example:

- Consider the following project hierarchy where the full name of the first class in file Form1.vb is ACME.WidgetApp.MyClass: Project1->Form1.vb->Form1.resx. Then the manifest resource name for the XML resource file Form1.resx would be `ACME.WidgetApp.MyClass.resources`.
- Consider the same project, except now Form1.resx is named Form1.de.resx. Since **de** is an RFC 1766 culture string supported by the Resource Manager, it is automatically included in the name of the resource. Consequently, in this case, the manifest resource name would become `ACME.WidgetApp.MyClass.de.resources`.
- Consider the same project, except now Form1.resx is named Form1.de-ff.resx. Although **de-ff** is a valid culture info string as per RFC 1766, it is not a culture info string that is supported by the .NET Framework Resource Manager. Therefore, de-ff will not be included in the resulting manifest resource name, and the manifest resource name would be the same as in the first example.

See Also

XML Resources Dependent Upon Invalid Code Files

Non-XML Resources

A non-XML resource file is any file whose **BuildAction** property is **EmbeddedResource** and whose extension is something other than .resx. All such resource files follow the same naming convention regardless of whether they are dependent files.

The naming for such files is as follows:

base_filename+[**.***optional RFC 1766 culture info string*]**.***extension*

Aside from file-system limitations, there are no restrictions on *base_filename*, the *optional RFC 1766 culture info string*, or *extension*.

See Also

Files Without Embedded Culture Info Strings | Files With Embedded Culture Info Strings | File Properties

Files Without Embedded Culture Info Strings

The project system uses the following convention for computing manifest resource names for a non-XML resource file without an embedded culture info string: the default namespace of the folder containing the resource file + the base filename + extension of the resource file.

Consider a project Project1 with root namespace RootNamespace and the following hierarchy: Project1->Folder1->picture1.jpg.

For Visual Basic, where the default namespace for every folder is always the root namespace, the computed manifest resource name for picture1.jpg would be `RootNamespace.picture1.jpg`.

For Visual C#, where the default namespace for every folder is always inferred from the folder's location in the hierarchy, the computed manifest resource name for picture1.jpg would be `RootNamespace.Folder1.picture1.jpg`.

See Also

Files With Embedded Culture Info Strings | Non-XML Resources

Files With Embedded Culture Info Strings

The project system uses the following convention for computing manifest resource names for a non-XML resource file with an embedded culture info string.

If the culture info string is supported by the .NET Framework Resource Manager, the assembly manifest resource name is computed as follows: the default namespace of the folder containing the resource file + the base filename of the resource file + the extension of the resource file.

If the culture info string is not supported by the .NET Framework Resource Manager, the assembly manifest resource name is computed as described in Files Without Embedded Culture Info Strings.

Consider a project Project1 with root namespace RootNamespace and the following hierarchy: Project1->Folder1->picture1.de-de.jpg.

For Visual Basic, where the default namespace for every folder is always the root namespace, the computed manifest resource name for picture1.de-de.jpg would be `RootNamespace.picture1.jpg`.

For Visual C#, where the default namespace for every folder is always inferred from the folder's location in the hierarchy, the computed manifest resource name for picture1.de-de.jpg would be `RootNamespace.Folder1.picture1.jpg`.

Consider the situation in the previous example, except the file picture1.de-de.jpg is now named picture1.de-ff.jpg. Although **de-ff** is a valid culture info string as per RFC 1766, it is not a culture info string that is supported by the .NET Framework Resource Manager. Therefore, de-ff will be included in the computed assembly resource name. In this case, the assembly resource name would be `RootNamespace.picture1.de-ff.jpg` for Visual Basic and `RootNamespace.Folder1.picture1.de-ff.jpg` for Visual C#.

Configuring Applications Using Dynamic Properties

With dynamic properties you can store some of an application's property values to an external file and load them when the application runs. This allows you to make changes to property values without recompiling the application, after your project has been deployed.

In This Section

Introduction to Dynamic Properties
Provides an overview of storing and retrieving property values.
Setting Dynamic Properties
Provides instructions on how to set a property to be stored in an external file.
Changing the Value of Dynamic Properties
Describes how to alter the value of a dynamic property after deployment.
Removing Keys from Properties
Describes how to change a dynamic property to one that is stored within the compiled application.
Walkthrough: Storing and Retrieving Dynamic Properties
Describes the major steps in storing and retrieving property values.

Related Sections

Deploying Applications and Components
Information about creating setup executables, packaging files, and publishing Web sites.
Saving the Properties of Components
Describes how to store and retrieve properties for custom controls.
Manageability
Discusses best practices for managing distributed applications.

Introduction to Dynamic Properties

Dynamic properties allow you to configure your application so that some or all of its property values are stored in an external configuration file rather than in the application's compiled code. By providing administrators with the means to update property values that may need to change over time, this can reduce the total cost of maintaining an application after the application has been deployed. For example, suppose you are building an application that uses a test database during the development process, and you need to switch it to a production database when you deploy it. If you store the property values inside the application, you have to manually change all of the database settings before you deploy, and then recompile the source code. If you store these values externally, you can make a single change in the external file and the application will pick up the new values the next time it runs.

> **Security Note** Property values stored in a configuration file are not secure. Sensitive data such as passwords and credit-card information should not be stored as dynamic properties.

You can use dynamic properties in any application that compiles to an .exe file. Projects that compile a DLL cannot use dynamic properties directly, however DLL properties can be set dynamically by the .exe referencing the .dll. Although the properties of any component, form, or control in these applications can be handled dynamically, some properties make better dynamic property candidates than others. Most often, you will store and retrieve properties that connect to external resources that might change, including databases, event logs, or performance counters. Many of these properties are identified as default candidates for dynamic properties. For more information, see "Default Dynamic Properties" below.

> **Note** The example code in this topic relies on the existence of a **SqlConnection** object and a configuration file; it will cause compilation errors without them. For more information on creating a **SqlConnection** object, see Walkthrough: Simple Data Access in a Windows Form. For more information on creating a configuration file, see Walkthrough: Storing and Retrieving Dynamic Properties.

Dynamic Properties and Configuration Files

When you set a property as configurable, its value is written to a configuration file and code is inserted in the class to indicate that the property value should be retrieved from this external resource. The configuration file varies based on the type of application; Web-based applications use the Web.config file, and Windows-based applications use a similar file with the extension .config. All of the forms and components in an application use a single configuration file. You cannot switch to a different configuration file or use multiple files within a single application.

Within the configuration file, properties are persisted via XML. For example, suppose you indicated that the **ConnectionString** property for a data connection should be stored in the configuration file. You would see this code in the Code Editor indicating that the value is stored externally:

```
' Visual Basic
Me.SqlConnection1.ConnectionString = CType(System.Configuration.ConfigurationSettings.AppSett
ings.GetValues("SqlConnection1.ConnectionString")

// C#
this.sqlConnection1.ConnectionString = ((string)( System.Configuration.ConfigurationSettings.
AppSettings.GetValues("SqlConnection1.ConnectionString"))));
```

> **Security Note** For more information about creating secure data connections, see Database Security.

In the configuration file, the value for this property would be stored via XML, using the key indicated in the form's code:

```
<configuration>
   <appSettings>
      <add key="sqlConnection1.ConnectionString" value="data source=myserver;initial catalog=
Apps;Integrated Security=SSPI;packet size=4096" />
   </appSettings>
</configuration>
```

Each value in the configuration file is assigned a key that is used to store and retrieve the value. The initial portion of the key indicates the component from which the value originated. For example, these two keys indicate a ConnectionString property on two different data connections within a single application:

```
<configuration>
```

```
  <appSettings>
    <add key="sqlConnection1.ConnectionString" value="data source=myserver;initial catalog=Ap
ps;Integrated Security=SSPI;packet size=4096" />
    <add key="sqlConnection2.ConnectionString" value="data source=myserver;initial catalog=Ap
ps;Integrated Security=SSPI;packet size=4096" />
  </appSettings>
</configuration>
```

You can modify the configuration file directly in order to dynamically update the property values in your application. The next time the application starts, it will update the values.

In a sense, configuration files are similar to resource files; both are used to store values outside the compiled application and both use XML to store their information. However, resource files serve a much different purpose than configuration files. Resource files are used to store strings and other localizable resources for translation purposes, while configuration files (in the case of dynamic properties) are used to update property values. The values in a resource file are meant to be translated but typically not changed, while the dynamic property values in a configuration file can be changed as needed. Also, you can associate multiple resource files with a project, but you can only have a single configuration file for your application. For more information on resource files, see Hierarchical Organization of Resources for Localization.

Setting Multiple Properties to the Same Key

Multiple properties can reference the same key-value pair in a configuration file. For example, if you have three components in your class that all access the same database, you can store the **ConnectionString** property for each in the same key-value pair. This means that if the database changes, you can update a single value in the settings file to apply the change to all three components. You would do this by setting each of the properties to the same key, like this:

```
' Visual Basic
Me.SqlConnection1.ConnectionString = CType(System.Configuration.ConfigurationSettings.AppSett
ings.GetValues("SqlConnection1.ConnectionString")
Me.SqlConnection2.ConnectionString = CType(System.Configuration.ConfigurationSettings.AppSett
ings.GetValues("SqlConnection1.ConnectionString")
Me.SqlConnection3.ConnectionString = CType(System.Configuration.ConfigurationSettings.AppSett
ings.GetValues("SqlConnection1.ConnectionString")

// C#
this.sqlConnection1.ConnectionString = ((string)(configurationAppSettings.GetValue System.Con
figuration.ConfigurationSettings.AppSettings.GetValues("SqlConnection1.ConnectionString"))));
this.sqlConnection2.ConnectionString = ((string)(configurationAppSettings.GetValue System.Con
figuration.ConfigurationSettings.AppSettings.GetValues("SqlConnection1.ConnectionString"))));
this.sqlConnection3.ConnectionString = ((string)(configurationAppSettings.GetValue System.Con
figuration.ConfigurationSettings.AppSettings.GetValues("SqlConnection1.ConnectionString"))));
```

Note that while the components in use differ, they all refer to the key for sqlConnection1.ConnectionString.

When you choose the same key for multiple properties, only one entry is made in the configuration file. The initial value stored is that from the first property that was given that key.

Data Types and Dynamic Properties

XML stores everything as a string. If the property value you are storing is not a string, you will see additional information in the Code Editor to indicate the data type for the property value. For example, suppose you are dynamically storing the value for a Timer component's **Interval** and **Enabled** properties. In the configuration file, this property would be stored like this:

```
<appSettings>
   <add key=timer1.Interval" value="100" />
   <add key=timer1.Enabled" value="True" />
</appSettings>
```

In the Code Editor, you would see this code to indicate that the retrieved value needs to be changed to a Double data type:

```
' Visual Basic
Me.Timer1.Enabled = System.Configuration.ConfigurationSettings.AppSettings.GetValues ("Timer1
.Enabled")
        Me.Timer1.Interval = System.Configuration.ConfigurationSettings.AppSettings.GetValues
```

```
("Timer1.Interval")

// C#
this.timer1.Enabled = ((bool)(configurationAppSettings.GetValue("timer1.Enabled", typeof(bool
))));

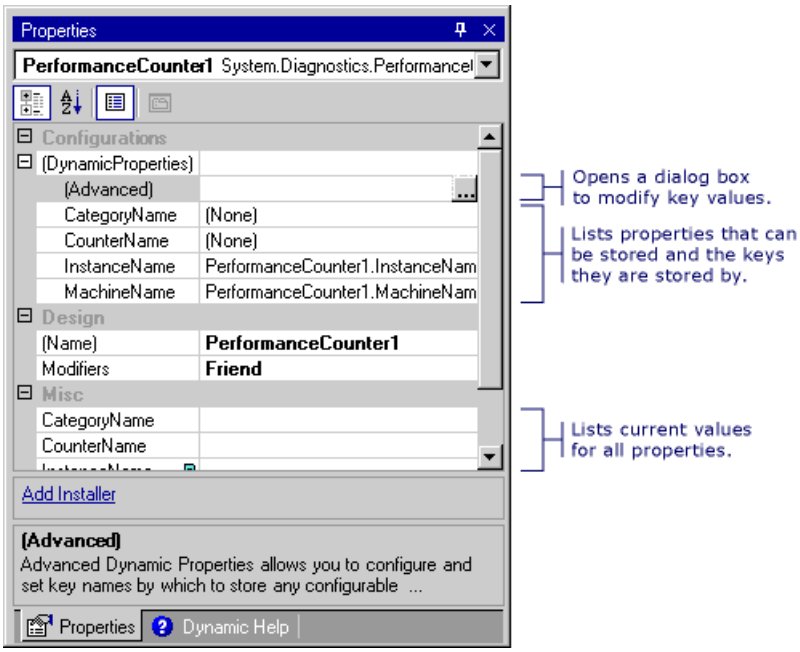
this.timer1.Interval = ((System.Double)(configurationAppSettings.GetValue("timer1.Interval",
typeof(System.Double))));
```

Note There are two timers, one for Windows Forms and one for server-based applications, with slight differences in programming models. This example uses the server-based timer. For more information on the two timers available, see Introduction to Server-Based Timers.

Default Dynamic Properties

By default, the **DynamicProperties** node of the Properties window lists component properties that are likely to be stored in an external file. The following figure shows the way the Properties window arranges these items:

Dynamic Properties in the Properties Window



If you want to dynamically store a value for a property that is not listed in the Properties window, you can do so by selecting the ellipsis next to the Advanced listing in this section of the Properties window. This opens the **Dynamic Properties** dialog box, which lists all of the properties with an elementary data type (such as Boolean, string, float, double, integer, short, and so on) for the current component or form.

Note that if no properties are listed in the **DynamicProperties** node of the Properties window, this means that there are no properties that are configurable by default for that component. However, you can still add properties using the dialog box.

Performance and Security Concerns with Dynamic Properties

There are two items that may be of concern when you use dynamic properties. First, dynamic property storage and retrieval may affect your application's performance somewhat. Retrieving property values from within the compiled application is slightly faster than retrieving properties values from the configuration file. The first time a configuration file value is accessed by the application, there will be a slight performance impact as the application reads the file. This impact is very minor, however, and should not be noticeable. Any subsequent retrieval of that or other properties has a much smaller performance impact — similar to reading a value from a hash table.

Second, if you are storing property values such as user IDs and passwords to an external file, you will want to control who has access to the file and the values it contains. One way to accomplish this is to secure your file with a Windows *access control list* (ACL). An access control list specifies what operations different users can perform on specific files and directories. In addition, if you are working with a Web-based application, you can take advantage of the integrated security option provided by Windows, Internet Information Services (IIS), and SQL Server. In that model, a user's authentication credentials for the local network are also used to access database resources, and no explicit user name or password are used in the connection string.

For details about security, see your Windows documentation or the following topics:

Walkthrough: Storing and Retrieving Dynamic Properties | Configuring Applications Using Dynamic Properties | Setting Dynamic Properties | Removing Keys from Properties | Changing the Value of Dynamic Properties

Setting Dynamic Properties

You use the Dynamic Properties dialog box to indicate on a property-by-property basis those values you want to write to the configuration file. By default, this dialog box lists each property that Microsoft has identified as being a likely candidate for configuration; for most components, this will be a subset of the available properties.

For each property you want to store, you identify the key that the value should be stored under in the project's configuration file. For example, if you are storing the **ConnectionString** property for a data connection called oledbConnection1, you might set the key for this value to be oledbConnection1.ConnectionString. The settings file would then store the current value of the **ConnectionString** property under this uniquely identified key.

To set a property to be dynamically stored

1. Access the Properties window for the form, control, or component for which you want to set up dynamic properties.
2. Set the values of any properties you want to store in the configuration file.
3. Expand the **DynamicProperties** node.
4. If the property you want to store is listed beneath this node, click the **Ellipsis** ( ) button next to it and do the following:
   a. Click **Map property to a key in configuration file**.
   b. If you want to change the value under which the property is stored, modify the setting of the **Key** field.
5. If the property you want to store is not listed, click the **Ellipsis** ( ) button next to the **Advanced** property, and perform these steps in the dialog box that appears:
   a. In the **Properties** list box, select the check box next to the property whose value you want to store in an external file.
   b. In the **Key Mapping** drop-down box, either accept the default key or type a new key value by which you want the property's value to be stored.
   c. Click **OK**.
6. Repeat step 4 or 5 for each property for which you want to store a value.
7. Click **OK** to close the dialog box.

   All of the properties you chose to store dynamically are now listed in the **DynamicProperties** node of the Properties window.

Introduction to Dynamic Properties | Removing Keys from Properties | Changing the Value of Dynamic Properties | Walkthrough: Storing and Retrieving Dynamic Properties

Changing the Value of Dynamic Properties

You change the value of a dynamic property after deployment by modifying the configuration file in which the property value was stored. You can modify the configuration file by double-clicking it in Solution Explorer, or by opening it in any editor from the application's deployed location. Depending on whether you are working with a Windows application or a Web application, your configuration file will be named differently:

- If you are using a Windows application, the design-time configuration file will be named app.config. After your project is compiled and deployed, the file will be copied to the bin directory and renamed to *assembly.config*, where *assembly* is the name of your project's assembly.
- If you are using a Web application, the information about dynamic properties is stored in AppSettings section of the Web.config file.

After making the change to the configuration file, the new property value will be incorporated the next time you start your application.

For example, suppose you have an instance of the **EventLog** component that you have connected to a custom log called Orders, and now you want to switch it to a different log called ProcessedOrders. The component instance's **Log** property was dynamically stored in the .config file, which would currently indicate the following:

```
<add key="eventLog1.Log" value="Orders" />
```

To change this, you would pull up the configuration file and change the value as follows:

```
<add key="eventLog1.Log" value="ProcessedOrders" />
```

To make a change to the value of a dynamic property after deploying your application

1. In an editor, open the configuration file for your application.
2. Locate the line that contains the property and value you want to modify. The line should look like this:

   ```
   <add key="Component.Property" value="currentvalue" />
   ```

   where *Component* is the name of the control or other element on which the property occurs, and *Property* is the name of the property whose value is being stored. *currentvalue* is the stored value for the property.
3. Modify the *currentvalue* portion of the statement to the new value you want to use.
4. Save and close the file.
5. Restart your deployed application.

   The new value will be updated automatically.

   > **Note** If you are working in a Web application, the application will automatically restart as soon as you modify the configuration file.

Introduction to Dynamic Properties | Setting Dynamic Properties | Removing Keys from Properties | Walkthrough: Storing and Retrieving Dynamic Properties

Removing Keys from Properties

You remove a key from a property when you no longer want to store that property's value in an external file. Removing a key removes the code indicating that the property value is stored in a configuration file.

Note that the system does not automatically update the configuration file when you remove a key from a property — the entry still appears in the configuration file. This is because the configuration file does not keep track of references to a key; because multiple properties may use the same key, the configuration file has no way of knowing when a key is no longer in use. Therefore, there may be many more keys in your configuration file than are actually in use in the product. This should not cause problems for your application.

To remove a key from a property

1. Access the Properties window for the form, control, or component.
2. Expand the **DynamicProperties** node. All properties that currently have keys are listed beneath this section.
3. Locate the property whose key you want to remove, then click the **Ellipsis** ( ) button next to it.
4. In the dialog box that appears, uncheck the **Map property to a key in configuration file** check box.

   When you return to the Properties window, that property will now show a value of **None** in the **DynamicProperties** node, indicating that its value is no longer being stored.

   > **Note** If you want, you can edit the configuration file to remove the entry for this property; however, leaving the property key in the file will not cause any errors in your application.

Introduction to Dynamic Properties | Setting Dynamic Properties | Changing the Value of Dynamic Properties | Walkthrough: Storing and Retrieving Dynamic Properties

Walkthrough: Storing and Retrieving Dynamic Properties

The procedures in this topic demonstrate the process of creating a project, storing some of its property settings in an external file, and then modifying the stored values and dynamically updating them in the deployed application.

In this application, you will create an instance of the Event Log component and store its property values to a file.

To create your component instance

1. On the **File** menu, point to **New**, and then click **Project**.
2. In the **New Project** dialog box, choose Visual Basic or Visual C# in the left pane, then choose the **Windows Application** template. Name it **MyLog**.
3. From the **Components** tab of the Toolbox, drag an **EventLog** component to the form.

   > **Note** Dynamic properties are not associated in any way with the **EventLog** component; you are simply using this component in this walkthrough as an example of the type of components whose properties you can store externally.

4. In the Properties window for the **EventLog** component, set the following values:
   - Set the **Log** property to **Application** so that your component can connect to a valid Windows event log.
   - Set the **MachineName** property to the name of the server on which the event log resides. Use a period (**.**) for the local machine.
   - Set the **Source** property to the string of your choice. In this case, you can use the name of your project.
5. On the **View** menu, click **Code** to open the Code Editor for Form1.
6. Expand the node titled **Windows Forms Designer generated code**.

   You should see a line showing the property value for the **Log** property, as follows:

   ```
   ' Visual Basic
   Me.EventLog1.Log = "Application"

   // C#
   this.eventLog1.Log = "Application";
   ```

7. Save your files.

   > **Note** For more information on creating **EventLog** component instances and setting their properties, see Logging Application, Server, and Security Events.

To display the log property value

1. In the designer, drag a label and a button from the **Windows Forms** tab of the Toolbox to Form1.
2. Double-click the button to open the Code Editor and access the **Button** control's **Click** event handler.
3. Add this code to the method:

   ```
   ' Visual Basic
   Label1.Text = "You are connected to the " & EventLog1.Log & " Log."

   // C#
   label1.Text = "You are connected to the " + eventLog1.Log + " Log.";
   ```

To configure the Log property for your component

1. In the Properties window for the **EventLog** component, click the plus sign (+) next to **Dynamic Properties**.
2. Select the **Ellipsis** ( ) button next to the **Log** property.
3. In the **Dynamic Property** dialog box that appears, select the **Map property to a key in configuration file** check box, then click **OK**.

   This indicates that the **Log** property value should be stored using the default key — the class name and property name. In

this case, the key will be **EventLog1.Log** or **eventLog1.Log**, depending on the programming language you are using.

4. Access the Code Editor for Form1, and find the **InitializeComponent** procedure for **MyLog**.

   You should see that code has automatically been changed to reflect that the value is now stored externally:

```
' Visual Basic
Me.EventLog1.Log = _
   CType(configurationAppSettings.GetValue("EventLog1.Log", _
   GetType(System.String)), String)
Me.EventLog1.Source = "MyLog"

// C#
this.eventLog1.Log =
   ((string)(configurationAppSettings.GetValue("eventLog1.Log",
   typeof(string))));
this.eventLog1.Source = "MyLog";
```

5. Save your files and build the project.
6. In Solution Explorer, double-click the .config file for your project to view it in the editor. You should be able to locate the entry for the **EventLog1.Log** property value:

```
' Visual Basic
<add key="EventLog1.Log" value="Application" />

// C#
<add key="eventLog1.Log" value="Application" />
```

7. Run your application. When you click the button, the label should say that you are connected to the Application log.
8. Close your application.

You also have the ability to modify the saved values outside of running the application. You might want to do this to set the initial values for an application.

To modify the stored value of the project .config file

1. In Notepad, open the .config file that is stored in the project folder.
2. Locate the **EventLog1.Log** entry you looked at in the previous procedure.
3. Change the value in that line to **System** or **Security**, and then save and close the file.
4. Press **F5** to run the application. When you click the button, the new value should be reflected.

The configuration file in the project folder is named App.config. When you build the project, it is copied to the output folder and renamed to *Assemblyname*.config, where *assemblyname* is the project output, for example, MyLibrary.dll or MyApplication.exe. You need to modify this copy of the .config file to affect a deployed application. For more information, see Changing the Value of Dynamic Properties.

To modify the stored value of the deployed .config file

1. In Notepad, open the .config file for your application from its built location (often the \bin or \obj\debug folder of the project folder).
2. Locate the **EventLog1.Log** entry you looked at in the previous procedure.
3. Change the value in that line to **System** or **Security**, and then save and close the file.
4. Run the application from its built location. This is the same folder where you modified the .config file in step 1. When you click the button, the new value should be reflected.

Windows Forms and Web Forms Recommendations

When designing applications that involve a user interface, you have two choices: Windows Forms and Web Forms. Both have full design-time support within the development environment and can provide a rich user interface and advanced application functionality to solve business problems. How, then, to decide which technology is appropriate for a given application?

Certain application considerations might make the choice obvious: For example, if you are creating an e-commerce Web site that will be accessible to the public over the Internet, then of course you would develop the application using Web Forms pages. If you are building a processing-intensive, highly responsive application that needs to take advantage of the full functionality of the client machine — such as an office productivity application — of course you would use Windows Forms. However, in other cases the choice might not be so clear.

In the sections that follow, you can find information about the features and characteristics of each type of technology that will help you determine which is most suited to your application.

Windows Forms

Windows Forms are used to develop applications where the client is expected to shoulder a significant amount of the processing burden in an application. These include classic Win32 desktop applications, the kinds that were traditionally developed in previous versions of Visual Basic and Visual C++. Examples include drawing or graphics applications, data-entry systems, point-of-sale systems, and games.

A common feature these applications share is that they rely on the power of the desktop computer for processing and high-performance content display. Some Windows Forms applications might be entirely self-contained and perform all application processing on the user's computer. Games are often written this way. Others might be part of a larger system and use the desktop computer primarily for processing user input. For example, a point-of-sale system often requires a responsive, sophisticated user interface that is created on the desktop computer, but is linked to other components that perform back-end processing.

Because a Windows application that uses Windows Forms is built around a Windows framework, it has access to system resources on the client computer, including local files, the Windows registry, the printer, and so on. This level of access can be restricted to eliminate any security risks or potential problems that arise from unwanted access. Additionally, Windows Forms can take advantage of the .NET GDI+ graphics classes to create a graphically rich interface, which is often a requirement for data-mining or game applications.

Web Forms

ASP.NET Web Forms are used to create applications in which the primary user interface is a browser. Naturally, this includes applications intended to be available publicly via the World Wide Web, such as e-commerce applications. But Web Forms are useful for more than just creating Web sites — many other applications lend themselves to a "thin front end" as well, such as an intranet-based employee handbook or benefits application. An important feature is that there is no distribution cost, since users already have installed the only piece of the application that they need— the browser.

Web Forms applications are, by definition, platform-independent — that is, they are "reach" applications. Users can interact with your application regardless of what type of browser they have and even what type of computer they are using. At the same time, Web Forms applications can be optimized to take advantage of features built into the most recent browsers such as Microsoft Internet Explorer 5 to enhance performance and responsiveness. (In many cases, this optimization is built into the Web Forms components you are using, which can automatically detect browser levels and render pages accordingly.)

Web Forms offer some features that are useful even in non-Web contexts. Because they rely on HTML, they are suitable for text-intensive applications of any sort, and especially those in which text formatting is important. Because browsers are usually limited in their access to a user's system resources, they are useful precisely in situations where you want to limit users' access to portions of your application.

Comparing Windows Forms and Web Forms

The following table provides a side-by-side comparison of different application criteria and how Windows Forms and Web Forms technologies address these criteria.

Feature/Criterion	Windows Forms	Web Forms

Deployment	Windows Forms allow "no-touch" deployment, where applications can be downloaded, installed, and run directly on the users' machines without any alteration of the registry.	Web Forms have no client deployment; the client requires only a browser. The server must be running the Microsoft .NET Framework. Updates to the application are made by updating code on the server.
Graphics	Windows Forms include GDI+, which allows sophisticated graphics to be used for games and other extremely rich graphical environments.	Interactive or dynamic graphics require round trips to the server for updates when used on Web Forms. GDI+ can be used on the server to create custom graphics.
Responsiveness	Windows Forms can run entirely on the client computer; they can provide the quickest response speed for applications requiring a high degree of interactivity.	If you know that users will have Internet Explorer 5 or later, a Web Forms application can take advantage of the browser's dynamic HTML (DHTML) capabilities to create a rich, responsive user interface (UI). If users have other browsers, most processing (including UI-related tasks such as validation) requires a round trip to the Web server, which can affect responsiveness.
Form and text flow control	Windows Forms grid positioning gives you precise two-dimensional control (x and y coordinates) over the placement of controls. To display text on Windows Forms requires that you insert it into controls (for example, the **Label** control, the **Textbox** control, or the **RichTextBox** control). Formatting is limited.	Web Forms are based around HTML-style flow layout and therefore support all the features of Web page layout. They are particularly rich in text formatting support. Control layout can be managed adequately (with some limitations, such as no overlapping controls). If the users have DHTML-capable browsers, you can specify much more precise layout with two-dimensional (x- and y-coordinate) layout.
Platform	Windows Forms require the .NET Framework running on the client computer.	Web Forms require only a browser. DHTML-capable browsers can take advantage of extra features, but Web Forms can be designed to work with all browsers. The Web server must be running the .NET Framework.
Access to local resources (file system, Windows registry, and so forth)	Applications, when permitted, can have complete access to local computer resources. If required, the application can be restricted with precision from using specific resources.	Browser security prevents the application from accessing resources on the local computer.
Programming model	Windows Forms are based on a client-side, Win32 message-pump mode, where instances of components are created, used, and discarded by the developer.	Web Forms rely on a largely asynchronous, disconnected model, where components are loosely coupled to the application front end. Typically, application components are invoked via HTTP. This model may not be suitable for applications requiring extreme throughput from the user end or for those with high-volume transactions. Similarly, Web Forms applications may not be suitable for database applications that require high levels of concurrency control (for example, pessimistic locking).
Security	Windows Forms use granular permissions in its implementation of code access security to protect computer resources and sensitive information. This allows careful exposure of functionality, while retaining security. For instance the Printing Permission, which at one level would allow printing to the default printer only, at another level would allow printing to any printer.	Authorization to gain access to the resources of a web application is typically controlled on a per-URL basis by authenticating the credentials (for example, a name/password pair) of the requestor. Web Forms enable the ability to control the identity under which server application code is executed. Applications can execute code with the identity of the requesting entity, which is known as impersonation. Applications can also dynamically tailor content based on the requestor's identity or role. For example, a manager could receive access to a site, or a higher level of content than someone with lower permissions.

Event Handlers in Visual Basic and Visual C#

You can use events to notify objects when interesting things happen. You can associate methods with particular events; these methods are called *event handlers*. When an event is raised, the event handler(s) that receive the event are executed. Events can be assigned to multiple handlers, and the methods that handle particular events can be changed dynamically.

There are subtle differences in the way that Visual Basic and Visual C# implement events and event handling. Those aspects that are similar for both languages are discussed in the same topic. Those aspects that different are discussed in language-specific topics.

Events and Delegates
Provides an overview of the event model and describes delegates in the .NET Framework.

Creating Web Applications and Services

An important part of Visual Studio .NET is the ability to create distributed applications based around the Web. Visual Studio .NET allows you to create the application user interface using Web Forms pages and to create components using XML Web services.

Web Forms is the ASP.NET technology that allows you to create a user interface for Web-based applications, whether customers are accessing your application from a traditional Web browser or a mobile device. Using Web Forms pages, you can create a browser-neutral UI that does its processing on the Web server, freeing you of the need to create browser-specific (or device-specific) versions of your user interface.

XML Web services are components that run on the server and typically include business logic. Like traditional components, they encapsulate specific functionality and can be called from different programs. However, they are available via Web protocols, making them compatible with programs running in different languages, on different computers, and even on different operating systems.

> **Note** You can also use Windows Forms as the user interface for a distributed ASP.NET Web application. For more information, see Windows Forms as the Presentation Tier of a Three-Tier Application.

Introduction to ASP.NET Web Applications in Visual Studio

Visual Studio .NET allows you to create applications that leverage the power of the World Wide Web. This includes everything from a traditional Web site that serves HTML pages, to fully featured business applications that run on an intranet or the Internet, to sophisticated business-to-business applications providing Web-based components that can exchange data using XML.

This topic provides an overview of the types of Web applications you can create in Visual Studio, how they relate to one another and to other Visual Studio technologies, and suggestions about where to learn more about the types of Web applications you want to create.

> **Note** For details about the relative advantages of Web applications and Windows applications, see Windows Forms and Web Forms Recommendations.

Visual Studio ASP.NET Web Applications

A Visual Studio Web application is built around ASP.NET. ASP.NET is a platform — including design-time objects and controls and a run-time execution context — for developing and running applications on a Web server.

ASP.NET in turn is part of the .NET Framework, so that it provides access to all of the features of that framework. For example, you can create ASP.NET Web applications using any .NET programming language (Visual Basic, C#, Managed Extensions for C++, and many others) and .NET debugging facilities. You access data using ADO.NET. Similarly, you can access operating system services using .NET Framework classes, and so on.

ASP.NET Web applications run on a Web server configured with Microsoft Internet Information Services (IIS). However, you do not need to work directly with IIS. You can program IIS facilities using ASP.NET classes, and Visual Studio handles file management tasks such as creating IIS applications when needed and providing ways for you to deploy your Web applications to IIS.

Where Does Visual Studio Fit In?

As with any .NET application, if you have the .NET Framework, you can create ASP.NET applications using text editors, a command-line compiler, and other simple tools. You can copy your files manually to IIS to deploy the application.

Alternatively, you can use Visual Studio. When you use Visual Studio to create Web applications, you are creating essentially the same application that you could create by hand. That is, Visual Studio does not create a different kind of Web application; the end result is still an ASP.NET Web application.

The advantage of using Visual Studio is that it provides tools that make application development much faster, easier, and more reliable. These tools include:

- Visual designers for Web pages with drag-and-drop controls and code (HTML) views with syntax checking.
- Code-aware editors that include statement completion, syntax checking, and other IntelliSense features.
- Integrated compilation and debugging.
- Project management facilities for creating and managing application files, including deployment to local or remote servers.

If you have used Visual Studio before, these kinds of features will seem familiar, because they are similar to features that you get for creating applications in previous versions of Visual Basic and Visual C++. With Visual Studio .NET you can use these kind of features to create ASP.NET Web applications.

Elements of ASP.NET Web Applications

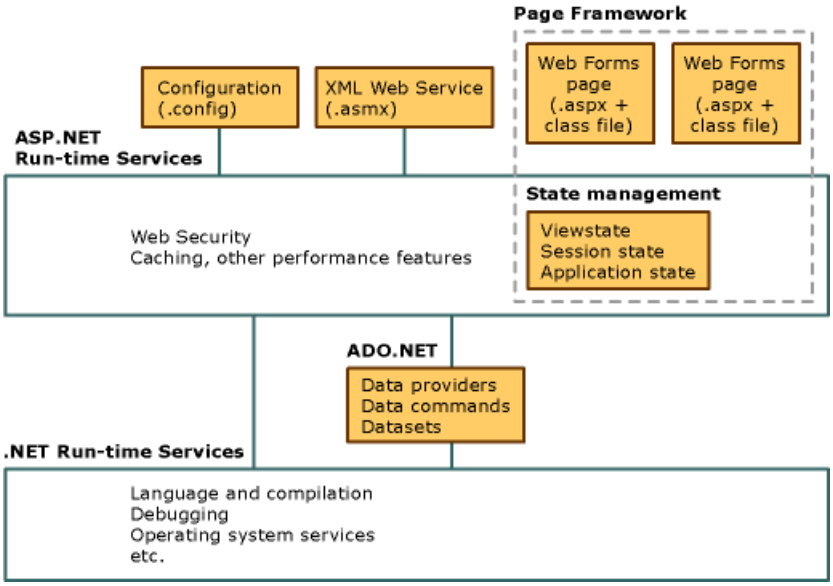
Creating ASP.NET Web applications involves working with many of the same elements you use in any desktop or client-server application. These include:

- **Project management features** When creating an ASP.NET Web application, you need to keep track of the files you need, which ones need to be compiled, and which need to be deployed.
- **User interface** Your application typically presents information to users; in an ASP.NET Web application, the user interface is presented in Web Forms pages, which send output to a browser. Optionally, you can create output tailored for mobile devices or other Web appliances.
- **Components** Many applications include reusable elements containing code to perform specific tasks. In Web applications, you can create these components as XML Web services, which makes them callable across the Web from a Web application, another XML Web service, or a Windows Form, for example.
- **Data** Most applications require some form of data access. In ASP.NET Web applications, you can use ADO.NET, the data

services that are part of the .NET Framework.

- **Security, performance, and other infrastructure features** As in any application, you must implement security to prevent unauthorized use, test and debug the application, tune its performance, and perform other tasks not directly related to the application's primary function.

The following diagram provides an overview of how the pieces of ASP.NET Web applications fit together and fit into the broader context of the .NET Framework.



The sections below outline the different elements of an ASP.NET Web application and provide links to more information about how to work with each element in Visual Studio.

Overview: ASP.NET

The information in this topic provides only an introduction to ASP.NET. For details about what ASP.NET is and what components are involved in an ASP.NET application, see Introduction to ASP.NET.

Project Management: ASP.NET Web Application Projects and Deployment

To work with an ASP.NET Web application using Visual Basic or Visual C#, you use the ASP.NET Web Application project template. As with other Visual Studio projects, a Web application project is a central repository for all the information required to design, run, and manage the application.

When you create a Web application project, Visual Studio creates the necessary files and folders on the server, sets the appropriate security settings on them, and creates the IIS application. For details, see ASP.NET Web Application Template.

Each Web application can maintain a Web.config file that follows the format and conventions of .NET configuration files. In ASP.NET, the configuration file allows you to establish project-specific settings for security, compilation options, tracing, error handling, and more.

For details about how to create and manage ASP.NET Web application projects in Visual Studio, see the following topics.

- Working with Web Projects Provides links to topics that describe Web application projects in Visual Studio.
- Web Forms Pages and Projects in Visual Studio Provides details about the types of files created in a Web Application project.
- Deployment of a Web Setup Project Provides an introduction to deploying Web applications.
- ASP.NET Configuration Describes the configuration file system and provides links to topics about the contents of the Web.config file.

User Interface: Web Forms and the ASP.NET Page Framework

You can create HTML pages and Web Forms pages as the user interface for your application. HTML pages are generally used for static content. In contrast, Web Forms pages give you a programmable interface that works much like a Visual Basic form, except that the user interface is rendered in a Web browser or other Web device.

> **Note** You can use a Windows Form as the user interface in an application that calls XML Web services. For an example, see Walkthrough: Creating a Distributed Application.

Web Forms pages are built on the ASP.NET Page framework. Each Web Forms page is an object that derives from the ASP.NET Page class, which acts as a container for controls. The page actually consists of two files: an .aspx file that contains the UI elements (static HTML text and control elements) and a class file that contains the code that runs the page. For details, see Introduction to Web Forms Pages.

When users request a Web Forms page, the Page framework runs the Web Forms page object and all the individual controls on it. The output of the **Page** class and of the controls is HTML. For details, see Web Forms Page Processing.

Because the Web is inherently stateless — by default, components in a Web application are alive only long enough to process a single request — Web applications face challenges in preserving values as the user works with the application. To help, the Page framework includes facilities for managing state. These include page-based "view state" (a method for preserving values in controls) and access to non-page-based state facilities such as Session state (user-specific) and Application state (global to the application). For details, see Web Forms State Management.

The Page framework supports a set of controls you can use to program user interaction with your Web Forms pages. User actions in the form are captured and processed by the Page framework in a way that lets you treat them as standard events. You can choose from a large selection of controls available in Visual Studio. In addition, you can create your own custom controls. For details, see Introduction to Web User Controls and Developing ASP.NET Server Controls.

> **Note** You can also create output for mobile devices. To do so, you use the same ASP.NET page framework, but you create Mobile Web Forms instead of Web Forms pages and use controls specifically designed for mobile devices. For details, see Creating ASP.NET Mobile Wep Applications.

For details about Web Forms pages and how to work with them in Visual Studio, see the following topics:

- Web Forms Pages Lists topics that provide an overview of Web Forms, including background on ASP.NET and on the Web Forms code model.
- Creating and Managing Web Forms Pages Provides information on how to create, add, and manage Web Forms pages.
- Programming Web Forms Provides information on the specific aspects of programming in a Web Forms environment.

Web-based Components: XML Web Services

An XML Web service is a component that can be called over a TCP/IP network by other applications. It performs a specific function — anything from calculations and credit card validation to complex order processing— and returns values to the calling application.

What makes XML Web services unique is that they can be called across the Web. XML Web services are invoked using HTTP or SOAP requests and exchange data with other components using XML. As such, they can form an integral part of ASP.NET Web applications, providing services not only to your applications, but also to any application that has Web access, making them ideal for business-to-business transactions.

For information about XML Web Services, how they work with ASP.NET applications, and how you can create them in Visual Studio, see Programming the Web with XML Web Services.

Web Application Data Access

Most ASP.NET Web applications involve at least some level of access to data. ASP.NET does not directly include data access facilities. Instead, Web applications use ADO.NET data services.

ADO.NET provides a complete framework for accessing and managing data from a variety of sources, including databases and XML files or streams. ADO.NET includes *providers* — classes that allow you to connect to data sources, execute commands, and read results. You can optionally keep data in a *dataset*, which is a disconnected, in-memory cache.

Data access in Web applications, whether in a Web Forms page or an XML Web service, introduces special challenges:

- **Statelessness** The components of Web applications usually do not preserve state, which makes it impractical to maintain live connections to a data source (or other resources).
- **Scalability** Because Web applications can have user loads that vary substantially over short periods of time, data access has to be designed with scalability in mind.

Visual Studio provides a variety of tools for working with data, including Toolbox support for data elements, various configuration wizards, and so on. The following topics provide information on data in general — that is, ADO.NET — as well as about using data in Web applications.

- Introduction to Data Access with ADO.NET Provides general information on the design of ADO.NET and some implications of the ADO.NET model for application development.

- Introduction to Data Access in Web Forms Pages Provides an overview of data access in Web applications, including information about some of the common issues associated with Web application data access.

Web Application Infrastructure: Security, Performance, and More

In addition to giving you the means to create user interface elements and callable components, ASP.NET provides a context for those elements to run in. For example, ASP.NET communicates with IIS to handle requests for Web Forms pages and XML Web services, parse the files, call related components, and so on.

Much of this work occurs beneath the surface, at a level where you do not typically need to program when you are creating desktop applications.

> **Note** Visual Studio provides limited support for working with ASP.NET infrastructure features. For example, you can edit the Web application configuration file (Web.config) using the Visual Studio Code Editor. But the .NET Framework is both pluggable and extensible, providing you with low-level access if necessary.

There are other aspects of Web applications that you must often contend with that are part of the application's infrastructure. These include:

- **Security** You frequently have to authenticate and authorize users of your Web application. There are special problems associated with security in a Web application, because users are getting access to server-based resources and because you have very little control over the client side of the application (the browser or mobile device). ASP.NET includes security features that you can configure and program against in your Web application.
- **Performance and optimization** You can tune your application's performance by caching pages and data. ASP.NET maintains an output cache that stores pages that have been requested before; by specifying caching settings, you can control how long pages are cached and under what circumstances they are refreshed.
- **Tracing** Because Web applications run on the server — often a remote server — they do not have output other than the application output (a Web Forms page, for example). ASP.NET therefore gives you the opportunity to include trace information directly in a Web Forms page. For details about adding tracing to ASP.NET Web applications, with links to topics that address specific trace procedures, see ASP.NET Trace.

For details about Web Forms **security**, see the following topics:

- Introduction to Web Application Security Describes the issues associated with security in Web Forms.
- Overview of Web Application Security Threats Provides a high-level discussion of the types of security vulnerability that Web applications are subject to.
- Basic Security Practices for Web Applications Provides a list of security recommendations that apply to even the simplest Web application.
- ASP.NET Web Application Security Provides an overview of security in ASP.NET, with links to a variety of topics about ASP.NET security architecture, security scenarios, and so on.
- Access Permissions for Web Applications Provides an introduction to the security context in which ASP.NET applications run.
- ASP.NET Configuration Explains a Web application configuration file system, which is where you make many security settings.

For details about Web Forms **performance and optimization**, see the following topics:

- ASP.NET Caching Features Provides an overview of the ASP.NET output cache facility for tuning performance, and links to caching procedures.
- ASP.NET Configuration Explains a Web application configuration file system, which is where you make many performance settings.
- Application Center Web site (http://www.microsoft.com/applicationcenter/) Provides information about testing Web application performance.

Code for Web Applications

This topic is designed to help you find code that demonstrates how to perform common programming tasks in Web applications using Visual Basic .NET.

Note For tasks that pertain to Web Forms controls specifically, see Code for Web Forms Controls.

The following categories are represented in the list below:

• Page Programming • Event Handling • Accessing Data • Managing State	• Error Handling • Security • XML Web Services • Related Code Examples

You can also find sample code for Web applications in the following locations:

- Web Applications Example Topics
- Web Forms Controls Example Topics
- Visual Basic Sample Applications
- Visual Basic QuickStarts and Other Samples
- .NET Framework Reference Information
- XML Web Services Created Using ASP.NET and XML Web Service Clients
- Creating ASP.NET Mobile Web Applications

Page Programming

Example of...

Creating a simple Web Forms page

Redirect users to another page

Passing information from one page to another

Detecting what browser the user has

Reading the query string passed in the URL

Event Handling

Example of...

Basic event handling for Web server controls

Creating event handlers at run time

Binding an existing method to an event

Handling an event in both client script and server code

Handling multiple events with the same event handler

Handling an event globally

Accessing Data

Example of...

Simple data access

Accessing read-only data

Caching datasets between round trips

Data-binding individual controls

Updating a database

Using a grid to read and write data

Displaying paged data

Defining a data source dynamically

Data-binding a list control (ListBox, DropDownList, etc)

Data-binding HTML server controls using HTML syntax

Data-binding controls at run time

Managing State

Example of...

Saving information in viewstate in the page

Sharing values in Session state

Saving a dataset in Session state

Error Handling

Example of...

Basic error handling

Creating a global error handler

Security

Example of...

Using HTML encoding to guard against malicious data

Filtering HTML elements out of user input

Allowing only predetermined characters in user input

Guarding against unhandled exceptions

Passing credentials to a database in a connection string

Storing information in the Windows registry on the server

XML Web Services

Example of...

Creating a simple XML Web service

Creating a simple application that consumes an XML Web service

Creating a simple XML Web service accessed from a Windows Form

Creating a simple distributed application using an XML Web service

Declaring an XML Web service

Inheriting from the base WebService class

Defining XML Web service methods

Exposing an XML Web service methods

Accessing an XML Web service

Accessing an XML Web Service asynchronously

Related Code Examples

Code for Data Access

Code Examples for Visual Basic Programmers

Web Walkthroughs

Walkthroughs give step-by-step instructions for common scenarios, which makes them a good place to start learning about the product or a particular feature area.

The following walkthroughs will help orient you to the use of Web Forms pages and the features of ASP.NET in your Visual Basic and Visual C# applications:

Creating a Basic Web Forms Page
: Illustrates the basic techniques of how to create a Web Forms page in Visual Basic or Visual C#, add controls to it, and run it.

Creating a Web Application Using Visual C# or Visual Basic
: Describes how to write a Web Forms application and then integrate a business-object component that gives you a 10% discount for purchases.

Creating a Web Application Using a Third-Party Business Object
: Describes how to write a Web Forms application using Managed Extensions for C++ and then integrate a third-party business-object component that gives you a 10% discount for purchases.

Validating User Input in a Web Forms Page
: Describes how to use Web Forms validation controls to check user entries without code, including required entries, data types, patterns, and specific values.

Displaying Data in a Web Forms Page
: Illustrates a basic data-access scenario, providing step-by-step instructions for how to create a Web Forms page that displays data in a grid control.

Creating Read-Only Data Access in a Web Forms Page
: Describes how use an ADO.NET data command and data reader to provide optimized access to read-only data in a Web Forms page.

Updating Data Using a Database Update Query in Web Forms
: Describes the basic techniques of creating a Web Forms page that uses a data command to update the database.

Using a DataGrid Web Control to Read and Write Data
: Gives step-by-step details on how to use a grid control to allow users to view and edit data.

Creating Paged Data Access using a Web Forms Page
: Describes how to create a Web Forms page that allows users to view data records a few records at a time, paging back and forth to view earlier and later records.

Creating a Web User Control
: Describes how to create a Web Forms user control — a page configured to act as a control — and use it on another page.

Converting a Web Forms Page to a User Control
: Describes how to convert a basic Web Forms page into a user control that can be hosted on another page.

Creating a Web Custom Control
: Describes how to create a custom control, add it to the toolbox, and use it on a Web Forms page.

Displaying an XML Document in a Web Forms Page using Transformations
: Gives step-by-step details on how to read an XML file and display it in different ways on a Web Forms page.

Security Considerations for ASP.NET Web Applications

Security is a vital aspect of your Web applications. The first step in creating a secure application is to understand what types of security issues arise in Web-based applications. You must also understand the basic strategies you use to protect the application and your system.

The topics listed below provide an introduction to security in Web applications. Because security is a broad subject, the "Related Sections" below provides links to places in the documentation where security is discussed in more detail.

In This Section

Introduction to Web Application Security
Provides an overview of security for Web applications, describing what types of issues you need to think about when creating applications in Visual Studio.

Web Application Security at Design Time in Visual Studio
Discusses the specific requirements for security that pertain to accessing resources you need during development. These requirements are distinct from those that apply to users of your application.

Web Application Security at Run Time
Discusses the security of your application when it is deployed and running.

Overview of Web Application Security Threats
Discusses the types of threats that your Web applications are subject to.

Basic Security Practices for Web Applications
Provides a list of the basic security recommendations that apply to all Web applications.

Scripting Exploits
Discusses ways that malicious users can send potentially damaging information to your application.

Protecting Against Script Exploits in a Web Application
Demonstrates how to use HTML encoding and HTML filtering to protect your application against malicious user input.

Displaying Safe Error Messages
Shows how to display error messages without giving away information that a malicious user might find helpful in attacking your system.

Access Permissions for Web Applications
Provides an overview of options for managing access to resources in a Web application.

Accessing SQL Server from a Web Application
Discusses design strategies for SQL Server access for your Web application.

Related Sections

Security Portal
Provides links to topics that provide an overview of security issues, including a bibliography.

Security Model
Discusses aspects of choosing a security model for a distributed application created using ASP.NET.

ASP.NET Web Application Security
Provides links to topics that describe how security works in the ASP.NET Framework.

Introduction to Web Application Security

Security is a critical part of your Web applications. Web applications by definition allow users access to a central resource — the Web server — and through it, to others such as database servers. By understanding and implementing proper security measures, you guard your own resources as well as provide a secure environment in which your users are comfortable working with your application.

This topic provides an overview of security for Web applications, describing what types of issues you need to think about when creating applications in Visual Studio. It also provides links to further information where you can learn more details about security features of Microsoft Internet Information Services (IIS) and of ASP.NET.

Authentication, Authorization, and Impersonation

Working with security requires that you understand these fundamental security concepts:

- *Authentication* confirms that users are who they say they are. For example, a user must provide a user name and password that are checked against an authority (a database, for example, or a Windows domain server).
- *Authorization* is the process of granting or denying access to resources for specific users.

These are concepts that are probably familiar from your use of Windows. In any sort of network, you log in (that is, you authenticate yourself). After doing that successfully, you can access specific files, folders, printers, and other resources — that is, you have authorization to get access to resources based on your login credentials. Windows provides a sophisticated security system that allows administrators to create user accounts and authorize those users to access folders, files, and so on.

There are security requirements in Web applications as well. However, the public nature of a Web application introduces some variations into this model. For example, in a public Web site, you would not expect every user to have to log into the computer or network where the Web server is running. To deal with this scenario, Web applications can *impersonate* users. Rather than requiring users to provide authentication credentials, a Web application might request a resource with some pre-established credentials.

Web Application Security in IIS and ASP.NET

Security for your Web application starts with the Web server (IIS). As a Windows-based service, IIS is fully integrated into Windows security. As with any other process, to access a file, IIS requires proper authentication. When users send a request from their browser to IIS, IIS must read the file from a Windows folder, and whatever Windows-defined authentication applies to the file applies to the IIS request as well. That is, to get access to a resource, IIS must provide proper credentials, the same as any other process.

When your Web applications run, they run under ASP.NET, which has its own security facilities. These come into play when your application requires access to resources. For example, if you want to read or write a file in your Web application, it is the ASP.NET security context that determines whether the request succeeds.

Not every user will have proper authentication to read files on a Windows server, however — particularly in Web applications available publicly on the Internet. IIS and ASP.NET therefore provide several mechanisms for establishing authentication. The descriptions below summarize these methods, necessarily leaving out many details about how the methods work. For details about IIS security, see the topics about access control in the IIS documentation on the Microsoft Web site (http://www.microsoft.com/windows2000/en/server/iis/). For details about ASP.NET security, see ASP.NET Web Application Security.

Anonymous Access

For applications where unknown users will be making requests (typically, public Web applications), IIS supports an "anonymous" user, namely, one who has no authentication credentials. In this scenario, the server on which IIS is running has an extra Windows user defined on it, with a user name of IUSR_<machinename>. This user account is typically defined with very restricted access rights.

When IIS gets a request from an unknown user, IIS turns around and makes the request to Windows using the <machinename>_anonymous user name as its credentials. That is, IIS impersonates the anonymous users for purposes of accessing the resource.

Basic and Digest Authentication

IIS also supports the Web-standard basic authentication model. In this scenario, users without credentials are prompted to supply a user name and password. These are returned to IIS where they become available to the application. Basic authentication

provides a useful way to provide restricted access in a public Web application. However, because the user passes a user name and password to IIS as clear text, it is not highly secure.

Digest authentication is similar to basic authentication, but uses encryption to send user information to the server. However, this style of authentication requires a Windows domain controller.

Windows Integrated Security

If the user making the request has already been authenticated in a Windows-based network, IIS can pass the user's credentials through when requesting access to a resource. (The credentials do not include the user name and password, only an encrypted token indicating the user's security status.) This is a typical scenario in a corporate intranet, where users log into the network before using your application. However, integrated security is not practical in applications that must go through firewalls. Even within the same network, integrated security has limitations for accessing resources that are on remote computers. For details, see Access Permissions for Web Applications.

Certificate Authentication

Finally, IIS supports the use of digital certificates and the secure sockets layer (SSL). In this scenario, either the server or the client has a certificate — a digital identification — that they have obtained from a third-party source. The certification is passed to your application with requests. It can be mapped to a Windows user account and granted appropriate permissions. This authentication has the advantage that, because each request or response is validated by the authority of the certificate, it lends itself to applications that require a trust relationship.

Web Application Security at Run Time

Developing your application requires that you work with one set of security issues. The other set of issues — and the ones that are generally more prominent in any discussion of Web security — address the security of your application when it is deployed and running.

Web applications by definition allow users access to a central resource — the Web server — and through it, to others such as database servers. By understanding and implementing proper security measures, you:

- Guard your own resources against unauthorized access.
- Restrict access levels by user or role.
- Establish data integrity and confidentiality, providing a secure environment in which your users are comfortable working with your application.
- Establish control over how your application can get access to restricted resources.
- Ensure that your application's code runs as intended.

This topic provides a general discussion of how you can accomplish these goals, and it includes links to additional topics where you can get more details on the technologies involved.

You can protect your application from unauthorized access by taking advantage of these types of security features:

- Security features offered by Internet Information Services (IIS) as part of its general Web server function. These include Windows file, computer, and user-level security.
- Security you can build into your ASP.NET application to provide application-specific access.

Security Process in ASP.NET

IIS provides a broad level of security for the Web site as a whole. However, IIS security mechanisms are very generic, in that the same mechanisms are used for all applications. Moreover, IIS security options — for example, using Windows integrated security — might not always be convenient for your application. (For intranet applications, on the other hand, you might want to use Windows integrated security for simplicity.)

Therefore, in order to provide more granular access to your application, you can use ASP.NET security. ASP.NET security works in conjunction with IIS security but extends it so that you can create more granular security and can customize features such as how you get user credentials.

IIS receives requests first from clients and performs any security checks that have been established for your application using IIS management tools. For example, if the application has been configured in IIS to allow anonymous access, IIS performs no credentials check. After performing this initial check of authentication, IIS sends the request to ASP.NET, which can perform a second level of checking. ASP.NET allows you to specify access restrictions in your application using a variety of criteria: you can restrict access to specific pages, or to specific users, and so on.

Authentication

ASP.NET supports the following ways to authenticate users. Several of them overlap with IIS authentication. For details, see Introduction to Web Application Security.

Authentication Type	Description
Anonymous Access	For applications where unknown users will be making requests (typically, public Web applications). Overlaps with IIS.
Basic and Digest Authentication	(Overlaps with IIS) In this scenario, users without credentials are prompted to supply a user name and password.

Windows Integrated Security (NTLM)	(Overlaps with IIS) If the user making the request has already been authenticated in a Windows-based network, IIS can pass the user's credentials through when requesting access to a resource.
Certificate Authentication	(Overlaps with IIS) In this scenario, the client has a certificate — a digital identification — that has been obtained from a third-party source. The certification is passed to your application with requests.
Kerberos	(Overlaps with IIS) Kerberos authentication protocol defines the interactions between a client and a network Authentication Service known as a Key Distribution Center (KDC). Windows 2000 implements a KDC as the authentication service on each domain controller. For details, see Basic Concepts for the Kerberos Protocol.
Forms authentication	If a user needs to be authenticated, ASP.NET redirects the request to a page that you specify. This page usually contains a form in which you get user name information. (For extra security, the form can be exchanged using HTTPS protocol.) When your application gets the form information, it can perform an application-specific check of the user's credentials. An important point is that the process of authentication is under your control (unlike that for IIS), which allows you to specify what the form looks like and how you choose to store user information. If a user is successfully authenticated, ASP.NET issues an encrypted cookie containing a token identifying the user for subsequent access.
Passport authentication	Using ASP.NET, you can check for users who have credentials they get from a Microsoft Passport-compliant application. If a user is successfully authenticated, ASP.NET issues an encrypted cookie containing a token identifying the user for subsequent access.

Forms authentication is generally the best choice in an ASP.NET application, because it gives you substantial control over how users are authenticated, and because it allows you to store an authentication in a token.

For details about IIS security, see the topic "About Access Control" in the IIS documentation on the Microsoft Web site (http://www.microsoft.com/windows2000/en/server/iis/). For details about ASP.NET authentication, see ASP.NET Authentication.

Authorization

When your Web application runs, it requests resources from the Web server and, often, from other processes as well, such as a database. The ASP.NET process runs in a user context that determines how your application will request those resources. By default, the ASP.NET process runs as a special local user, called ASPNET, with limited permissions. You can specify a different user context for the ASP.NET process, including "system" (which runs your application in administrator context) or a user whose credentials you explicitly provide.

In your ASP.NET application, you can specify that different users have authorized access to different resources. If your application is using Windows authentication, you can use Windows permissions to determine authorization to access specific files or folders on the server.

Alternatively, you can use URL-based authorization, in which authorization can be granted or denied according to different criteria:

- Specific users, or identities, which are based on the credentials provided by the user.
- Roles, which are entities defined to allow multiple users to share privileges based on a common role or function.
- Verbs, which are the HTTP processes (such as GET and POST) for accessing portions of your application.

For example, you can specify that all users can get pages (perform the GET verb) from your application, but that only specific users can post pages to it. Similarly, you might specify that all users are allowed to GET pages but specific roles are denied the right to post.

You can grant URL authorization for the application as a whole or on a directory-by-directory basis. A typical use is to allow all users to view pages in a public directory, but to keep restricted pages in a different directory that is authorized only for specific users or roles.

For more information, see Authorization, ASP.NET Authorization, and Access Permissions for Web Applications.

ASP.NET Configuration Files

You establish ASP.NET security choices using settings in a Web.config configuration file. The file allows you to include predefined

elements for various security options, including sections for authentication and authorization. The relevant sections of the Web.config file might look like the following:

```
<authentication mode="Forms">
   <forms name="login.aspx" loginUrl="[url]" >
      <credentials passwordFormat="SHA1">
         <user name="Mary" password="9611E4F94EC4972D5A537EA28C69F89AD28E5B36"/>
      </credentials>
   </forms>
</authentication>

<authorization>
   <allow verb="GET" users="*" />
   <allow verb="POST" users="Mary" />
   <deny verb="POST" users="*" />
</authorization>

<identity impersonate ="false"/>
```

Your application can contain more than one configuration file. By default, there is a configuration file at the application root that specifies security for the application as a whole — that is, security settings are inherited by subfolders. However, you can also create configuration files in individual folders to create security settings for that folder.

For more information, see ASP.NET Architecture and Forms Authentication Using an XML Users File.

XML Web Service Security

XML Web services run as Web applications using ASP.NET and therefore participate in the same security model as any ASP.NET application. For example, an XML Web service might be configured to use Basic authentication or Windows integrated security.

At design time, when you attempt to add a reference to an XML Web service — that is, when you request the XML Web service's discovery documents — the XML Web service will perform standard Web application authentication according to how it was configured. For example, if the XML Web service is configured to use Basic authentication, it will expect to get a user name and password from the requesting client. In Visual Studio, you typically use the Add Web Reference dialog box to discover XML Web services. If the XML Web service is using Basic authentication, for example, the Add Web Reference dialog box will prompt you for credentials.

If you are building an application that includes calls to an XML Web service, you need to be sure that you have appropriate credentials before making the call, or the call will fail. At run time, you can pass credentials to the XML Web service by setting the Credentials property of the client-side object representing the XML Web service before you call its methods.

Because other ASP.NET security options might not be sufficiently flexible, XML Web services can implement a custom authentication solution in which credential information is passed in SOAP headers. In this solution, credentials are passed in an optional part of the message exchanged between client and server. You can then write a custom **HttpModule** (implementing the IHttpModule interface) that can listen for the information in the header and call your authentication code.

As with other ASP.NET applications, the XML Web service might implement specific role-based authorizations to limit access to specific parts of the application.

For details, see XML Web Services Infrastructure and Securing XML Web Services Created Using ASP.NET.

Establishing Data Integrity and Confidentiality

Authentication and authorization establish who your users are and what resources they can access. These security features are designed primarily to protect your Web application from unauthorized use.

However, there is a separate aspect to security as well, which is to protect your users' information and provide them with the confidence that they can exchange sensitive information with you. For example, if your application asks users for credit card or other account numbers, personal information, or any data that users might not want others to know, you must provide a way for them to submit this information to you securely.

The solution is to use the Secure Sockets Layer (SSL) of IIS. This allows users to exchange encrypted information with you using HTTPS (secure) protocol. SSL provides security in both directions: your information is transmitted to the user using encryption, and information the user posts to your application is likewise encrypted.

Establishing SSL and Encryption

To use SSL and encryption, you must obtain a server certificate for your company or identity. The certificate is a digital signature that identifies your site in a way that cannot be impersonated. For Internet (public) applications, you obtain a server certificate from a recognized third-party certification authority. For private (intranet) applications, you can issue a server certificate yourself. You might do this to secure an internal application such as a personnel site.

Your server certificate also enables you to use encryption. SSL uses an encryption method called *public key encryption*. In this form of encryption, there are two keys: a public key used to encrypt data and a private key that you keep secret and use to decrypt information encrypted with the public key. The server certificate you obtain includes a public key. When users want to use SSL, your application sends the certificate and the public key to the browser. The browser and server then use the public key to establish a way to encrypt their information exchange.

> **Note** Using SSL requires that the browser support an encryption strength of at least 40 bits. This level is available in most browsers.

Once you have obtained a server certificate, you can instruct users to use SSL by having them use https:// as the prefix for getting and posting Web pages. IIS and the browser will automatically use an encrypted channel to exchange information.

For details on how to implement SSL, see Microsoft Knowledge Base article Q307267, "HOW TO: Secure XML Web Services with Secure Socket Layer in Windows 2000." For information on encryption, see Cryptography Overview. For information about certificates and about configuring SSL, see the topics in the IIS documentation on the Microsoft Web site (http://www.microsoft.com/windows2000/en/server/iis/).

Using .NET Code Security

A final aspect of security is in ensuring that the code in your application is protected from misuse, whether by being inadvertently run in an improper context or by being used in a malicious way. Because ASP.NET is part of the .NET Framework, you can also take advantage of code access security and role-based security to establish permissions for what code is allowed to do. For information, see ASP.NET Process Identity, Database Security, and Code Access Security.

Overview of Web Application Security Threats

Someone is going to try to hack your Web application. That is, if unknown users can get to your Web application, the odds are almost certain that someone will try to do something unauthorized or even malicious to your application. Most servers that are accessible to the public on the Internet are typically probed for vulnerabilities at least four or five times a day.

Therefore, no matter what your Web application is, you should build security into it. You should think about security the same way that you do about backup. Although you might not think that you will ever have a problem, it is always safest to assume that you will and to take precautions, just in case.

Perfect Security is Impossible

The first lesson about Web application security is that there is no such thing as perfect security. Even in secure systems, malicious users can wield sophisticated tools to try to get into your system. Fortunately, most attacks come from relatively unsophisticated users who simply look for sites that are easy to break in to.

Your initial goal should be to protect your site from the common and redundant exploits that comprise the vast majority of attacks.

Security Technology Is Only Part of the Solution

Implementing security is only part of the solution. Another important part is vigilance. Even if your system has many security safeguards, you need to watch it closely in these ways:

- Monitor your system's event logs. Watch for repeated attempts to log into your system or for a very high number of requests against your Web server.
- Learn about and install the latest security patches from Microsoft and other vendors. For example, the Microsoft security site (www.microsoft.com/security) has a list of the latest security bulletins for all Microsoft products. Other vendors have similar sites.

Threat Modeling

An important part of building a secure application is to understand the threats to it. Microsoft has developed a way to categorize threats that goes by the acronym STRIDE (Spoofing-Tampering-Repudiation-Information disclosure-Denial of service-Elevation of privilege). The sections below briefly describe these threats and how they apply to Web applications. For more information, see Designing for Securability.

Spoofing

To *spoof* is to impersonate a user or process in an unauthorized way. At its simplest, spoofing can mean typing in a different user's credentials. A malicious user might also change the contents of a cookie to pretend that he is a different user or that the cookie comes from a different server.

In general, you can prevent spoofing by using stringent authentication. Any time someone requests access to non-public information, make sure they are who they say they are. You can also defend against spoofing by keeping credential information safe. For example, do not keep a user name (or worse, a password) in a cookie, where a malicious user can easily find or modify it.

Tampering

Tampering means changing or deleting a resource without authorization. One example is defacing a Web page, where the malicious user gets into your site and changes files. An indirect way to tamper is using a *script exploit*. A malicious user manages to get code (script) to execute by masking it as user input from a form or as a link.

A primary defense against tampering is to use Windows security to lock down files, directories, and other Windows resources. The application should also run with the minimum privileges it can. You guard against script exploits by being extremely distrustful of any information that comes from a user or even from a database. Whenever you get information from an untrusted source, sanitize it by making sure it does not contain any executable code.

Repudiation

A repudiation threat is to hide evidence of an attack. In a Web application, this can mean impersonating an innocent user's credentials. You can guard against repudiation by, again, using stringent authentication. In addition, use the logging features of Windows to keep an audit trail of any activity on the server. For details, see Event Logging in the Platform SDK documentation.

Information Disclosure

Information disclosure simply means stealing or revealing information that is supposed to be private. A classic example is stealing passwords, but it can involve access to any file or resource on the server.

The best defense against information disclosure is to have no information to disclose. For example, if you avoid storing passwords, malicious users cannot steal them. (An alternative to storing passwords is to store only a hash of the password. When a user presents credentials, you can hash the user's password and compare only the hashes of the two.) If you do store secrets, use Windows security to secure it. As always, you should use authentication to be sure that only authorized users get access to restricted information. You can also encrypt information to help keep it secret.

Denial of Service

A *denial of service* attack is to deliberately cause an application to be less available than it should be. A typical example is to overload a Web application so that it cannot serve ordinary users. Alternatively, malicious users might try to simply crash your server.

IIS allows you to *throttle* applications, which means that it limits the number of requests it will serve. You might be able to deny access to users or IP addresses known to be malicious. Protecting against crashes is a matter of running robust code. You should test your application thoroughly and recover gracefully from error conditions, if possible.

Elevation of Privilege

An elevation of privilege is to use malicious means to get more permissions than normally assigned. For example, in a successful elevation of privilege attack, a malicious user manages to get administrative privileges to your Web server, giving themselves a free hand to wreak havoc.

To protect against elevation of privilege, run the application in a least-privilege context if practical. For example, it is recommended that you do not run ASP.NET applications as the SYSTEM (administrative) user.

Basic Security Practices for Web Applications

The topic of creating a secure Web application is a long one. It requires study to understand security vulnerabilities. You also need to familiarize yourself with the security facilities of Windows, the .NET Framework, and ASP.NET. Finally, it is essential to understand how to use these security features to counter threats.

However, even if you are not experienced with security, there are basic measures that you should take to protect your Web application. The list below provides minimum-security guidelines that apply to all Web applications.

- General Web Application Security Recommendations
- Run Applications with Least Privileges
- Know Your Users
- Guard Against Malicious User Input
- Access Databases Securely
- Create Safe Error Messages
- Keep Secrets Safely
- Use Cookies Securely
- Guard Against Denial-of-Service Threats

General Web Application Security Recommendations

Some of the most basic security recommendations are also the most obvious ones. However, even the most elaborate application security can fail if a malicious user can use simple ways to get to your computers.

- Back up often and keep your backups physically secure.
- Keep your Web server computer physically secure so that unauthorized users cannot get to it, turn it off, take it, and so on.
- Use the Windows NTFS file system, not FAT32. NTFS offers substantially more security than FAT32. For details, see the Windows documentation.
- Secure the Web server computer and all computers on the same network with strong passwords.
- Secure IIS. For details, see the article Manage Security of Your Windows IIS Web Services in the Microsoft security Web site (http://microsoft.com/technet/treeview/default.asp?url=/technet/security/bestprac/mcswebbp.asp).
- Close unused ports and turn off unused services.
- Run a virus checker that monitors traffic.
- Establish and enforce a policy that forbids users from keeping their passwords written down in an easy-to-find location.
- Use a firewall. For recommendations, see Checklist: Install a Firewall) on the Microsoft security site. (http://microsoft.com/security/articles/firewall.asp)
- Learn about and install the latest security patches from Microsoft and other vendors. For example, the Microsoft security site (www.microsoft.com/security) has a list of the latest security bulletins for all Microsoft products. Other vendors have similar sites.
- Use Windows event logging and examine the logs frequently for suspicious activity. This includes repeated attempts to log on to your system and an extremely high number of requests against your Web server.

Run Applications with Least Privileges

When your application runs, it runs within a context that has specific privileges on the local computer and potentially on remote computers. Follow these guidelines:

- Run the application in the context of a user with the minimum practical privileges. By default, under IIS version 5, an ASP.NET application runs in the context of a local user called ASPNET. In IIS 6 on Windows Server 2003, the account is called NETWORK SERVICE.For details, see ASP.NET Process Identity and Configuring ASP.NET Process Identity.
- Do not run your application within the context of a system user (administrator).
- Set permissions (ACLs, or Access Control Lists) on all the resources required for your application. Use the least permissive setting. For example, if practical in your application, set files to be read-only. For details, see the Windows documentation.
- Keep files for your Web application in a folder below the application root. Do not allow users the option of specifying a path for any file access in your application. This helps prevent users from getting access to the root of your server.
- Do not make anyone a member of the Debugger Users group who does not need to debug Visual Studio applications. This group has higher privileges than the VS Developers group. For details, see Adding Debugger Users and Configuring DCOM.

Know Your Users

In many applications, it is possible for users to access the site without having to provide credentials. If so, your application accesses resources by running in the context of a predefined user. By default, this context is the local ASPNET user (Windows 2000 or Windows XP) or NETWORK SERVICE user (Windows Server 2003) on the Web server computer.

To restrict access to users who are authenticated, follow these guidelines:

- If your application is an intranet application, configure it to use Windows integrated security. That way, the user's logon credentials can be used to access resources.
- If you need to gather credentials from the user, use one of the ASP.NET authentication strategies. For more information, see ASP.NET Authentication. For an example, see Simple Forms Authentication.

Guard Against Malicious User Input

As a general rule, never assume that input you get from users is safe. It is easy for malicious users to send potentially dangerous information from the client to your application. To guard against malicious input, follow these guidelines:

- In forms, filter user input to check for HTML tags, which might contain script. For details, see Protecting Against Script Exploits in a Web Application.
- Never echo (display) unfiltered user input. Before displaying untrusted information, encode HTML to turn potentially harmful script into display strings.
- Similarly, never store unfiltered user input in a database.
- If you want to accept some HTML from a user, filter it manually. In your filter, explicitly define what you will accept. Do not create a filter that tries to filter out malicious input; it is very difficult to anticipate all possible malicious input.
- Do not assume that information you get from the header (usually via the Request object) is safe. Use safeguards for query strings, cookies, and so on. Be aware that information the browser reports to the server (user agent information) can be spoofed, in case that is important in your application.
- If possible, do not store sensitive information in a place accessible from the browser, such as hidden fields or cookies. For example, do not store a user name or password in a cookie.

> **Note** View state is stored in a hidden field in an encoded format. By default, it includes a message authentication code (MAC) so that the page can determine whether view state was tampered with.

Access Databases Securely

Databases typically have their own security. An important aspect of a secure Web application is designing a way for the application to access the database securely. Follow these guidelines:

- Use the inherent security of your database to limit who can access database resources. The exact strategy depends on your database and your application:
  - If practical in your application, use integrated security so that only Windows-authenticated users can access the database. Integrated security is more secure than using connection strings.
  - If your application involves anonymous access, create a single user with very limited permissions, and perform queries by logging on as this user.
- Do not create SQL statements by concatenating strings that involve user input. Instead, create a parameterized query and use user input to set parameter values. For details, see Parameters in Data-Adapter Commands.
- If you must store a user name and password somewhere to use as the database login credential, store them securely. If practical, encrypt them. For details, see Encrypting and Decrypting Data. For an introduction to encryption, see Geek Speak Decoded #9: Cryptography and Encryption.

Create Safe Error Messages

If you are not careful, a malicious user can deduce important information about your application from the error messages it displays. Follow these guidelines:

- Do not write error messages that echo information that might be useful to malicious users, such as a user name.
- Configure the application not to show detailed errors to users. If you want to display detailed error messages for debugging, check first that the user is local to the Web server. For details, see Displaying Safe Error Messages.
- Create custom error handling for situations that are prone to error, such as database access.

Keep Secrets Safely

Secrets are any information that you do not want someone to know. A typical secret is a password or an encryption key. Of course, if a malicious user can get to the secret, then the data protected by the secret is compromised. Follow these guidelines:

- If your application transmits sensitive information between the browser and the server, consider using the Secure Sockets Layer (SSL). For details on how to implement SSL, see Microsoft Knowledge Base article Q307267, "HOW TO: Secure XML Web Services with Secure Socket Layer in Windows 2000."
- If you must store secrets, do not keep them in a Web page, even in a form that you think people will not be able to see it (such as in server code).
- If you encrypt information, do not create your own encryption algorithm. Use the Windows Data Protection API (DPAPI).

Use Cookies Securely

Cookies are an easy and useful way to keep user-specific information available. However, because cookies are sent to the browser's computer, they are vulnerable to spoofing or other malicious use. Follow these guidelines:

- Do not store any critical information in cookies. For example, do not store a user's password in a cookie, even temporarily. As a rule, do not keep anything in a cookie that, if spoofed, can bring you trouble. Instead, keep a reference in the cookie to a location on the server where the information is.
- Set expiration dates on cookies to the shortest practical time you can. Avoid permanent cookies if possible.
- Consider encrypting information in cookies.

Guard Against Denial-of-Service Threats

An indirect way that a malicious user can compromise your application is by making it unavailable. The malicious user can keep the application too busy to service other users, or if nothing else can simply crash the application. Follow these guidelines:

- Close or release any resource you use. For example, always close data connections and data readers, and always close files when you are done using them.
- Use error handling (for example, try-catch). Include a finally block in which you release resources in case of failure.
- Configure IIS to use process throttling, which prevents an application from using up a disproportionate amount of CPU time. For details, see the technical article Using the New Features in Internet Information Server 5.0: Part 1.
- Test size limits of user input before using or storing it.
- Put size safeguards on database queries. For example, before you display query results in a Web Forms page, check that there are not an unreasonable number of records.
- Put a size limit on file uploads, if those are part of your application. You can set a limit in the Web.config file using syntax such as the following, where the `maxRequestLength` value is in kilobytes:

```
<configuration>
   <system.web>
        <httpRuntime maxRequestLength="4096" />
   </system.web>
</configuration>
```

Scripting Exploits

From the perspective of a browser, a Web page is simply a long string of characters. The browser processes the string sequentially, displaying some characters while interpreting other characters such as `<b>` and `<script>` according to special rules. If a malicious user can insert some of those special characters into a page, the browser will not know that the characters are not supposed to be there, and it will process them as part of the page.

A simplistic script exploit might work as follows. Imagine an application that allows users to post comments about the latest movies for other users to read. The exploit steps might be:

1. The application displays a form where users enter comments. The malicious user writes a comment that includes a `<script>` block in it.
2. The form is posted and the malicious user's comment is stored in a database.
3. Another user visits the site. When the page is constructed, it reads comments out of the database and puts them into the page. The malicious user's `<script>` block is written into the page as if it were a text comment.
4. When the second user's browser displays the page, it gets to the `script` block and executes it.

There are other ways that malicious users can exploit script as well. The common thread is that most script exploits require the application to accept the malicious input and inject it (echo it) into a page where it will be executed by the browser. The potential damage from such an exploit depends on the script that is executed. It can be trivial, such as an annoying message that pops up in the browser. But it can also do serious damage by stealing cookies, stealing user input (such as a password), and if Internet security is lax, even running native code on the user's computer.

For information about preventing scripting exploits, see Protecting Against Script Exploits in a Web Application.

SQL Statement Exploits

A variation on a script exploit is one that causes malicious SQL statements to be executed. This can occur if an application prompts users for information and then concatenates the user's input into a string representing the SQL statement. For example, an application might prompt for a customer name with the intention of executing a statement such as the following:

```
"Select * From Customers where CustomerName = " & txtCustomerName.Value
```

But a malicious user who knows something about the database could use the text box to enter an embedded SQL statement with the customer name, resulting in a statement like the following:

```
Select * From Customers Where CustomerName = 'a' Delete From
Customers Where CustomerName > ''
```

When the query is executed, the database is compromised.

Guarding Against Scripting Exploits

The primary defense against scripting exploits is to simply never trust information coming from a user. Assume that any data posted to your application from a browser can contain malicious script.

Similarly, any time that you write a string into a page, you should assume the string could contain malicious script. (Unless you programmatically created the string yourself.) For example, when you read strings out of a database, you should assume that they can contain malicious script. The most security-conscious developers distrust even their own databases, on the theory that a malicious user might have found a way to tamper with the database.

ASP.NET provides you with several ways to protect against scripting exploits:

- ASP.NET protects you against this automatically with request validation. By default, if the Request object contains HTML-encoded elements or certain HTML characters (such as `—` for an em dash), the ASP.NET page framework raises an error. It is recommended that you create a handler in your application for this error.
- If you want to display strings in your application but do not trust them, apply HTML encoding to them. For example, with encoding, the tag `<b>` becomes `<b>`. You might do this if the strings you are displaying are from a database whose contents you are not sure you can trust.
- If you want your application to accept some HTML (for example, some formatting instructions from users), turn off automatic checking and create a filter that defines exactly what HTML the application will accept.

Security Note Never disable automatic request validation without adding your own checks or filter.

Note Do not create a filter that attempts to filter out only unacceptable elements, because it is difficult to anticipate every possible bad input. Instead, if you do create a filter, create one that has a defined list of acceptable input.

- To protect against SQL statement exploits, never create SQL queries using string concatenation. Instead, use a parameterized query and assign user input to parameter objects. For details, see Parameters in Data-Adapter Commands.

Protecting Against Script Exploits in a Web Application | Overview of Web Application Security Threats | Basic Security Practices for Web Applications | Security Portal

Protecting Against Script Exploits in a Web Application

Most scripting exploits occur when users can get executable code (script) into your application. By default, ASP.NET provides request validation, which raises an error if a form post contains any HTML whatsoever.

You can protecting against script exploits in these ways:

- Apply HTML encoding to strings before accepting or displaying them, so that the strings do not include any executable elements.
- If your application needs to accept some HTML, disable request validation and create your own HTML filter.

The procedures in this topic describe how to perform these tasks.

Applying HTML Encoding

HTML encoding converts HTML elements using HTML reserved characters so that they are displayed rather than executed.

To apply HTML encoding

- Before displaying strings, call the Server object's HtmlEncode method. HTML elements are converted into string representations that the browser will display rather than interpret as HTML.

  The following example illustrates HTML encoding. In one instance, the user input is encoded before being displayed. In the second instance, data from a database is encoded before being displayed.

  > **Note** This example will only work if you disable request validation in the page by adding the @ Page attribute ValidateRequest="false" . Never disable request validation without adding your own check or filter.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e _
      As System.EventArgs) Handles Button1.Click
   Label1.Text = Server.HtmlEncode(TextBox1.Text)
   Label2.Text = _
       Server.HtmlEncode(dsCustomers.Customers(0).CompanyName)
End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e)
{
    Label1.Text = Server.HtmlEncode(TextBox1.Text);
    Label2.Text =
        Server.HtmlEncode(dsCustomers1.Customers[0].CompanyName);
}
```

Filtering HTML Elements

By default, Web Forms pages detect any HTML elements and reserved characters in information posted to the server. This prevents users from trying to embed script into your application. When the page detects HTML, it raises an error. You can catch this error using a **Page_Error** or **Application_Error** handler. For details, see Displaying Safe Error Messages.

However, if your application needs to accept some HTML elements, turn off request validation and create a filter that allows only the HTML elements that you want to accept.

> **Note** Do not create a filter that attempts to filter out only unacceptable elements, because it is difficult to anticipate every possible bad input. Instead, if you do create a filter, create one that defines acceptable input.

To filter HTML elements

1. Disable request validation by the adding the attribute `ValidateRequest="false"` to the @ Page directive.

   > **Security Note** Never disable automatic request validation without adding your own checks or filter.

2. Encode the string using the HtmlEncode method.
3. Call the String.Replace method to convert the encoded HTML tags you want to accept back to their HTML forms.

> **Tip** If you are familiar with regular expressions, you can use one to perform the filtering efficiently. For details, see .NET Framework Regular Expressions.

The following example illustrates a simple filter that accepts bold and underscore elements (, , <u>, </u>). All other user input is encoded before being displayed.

> **Security Note** Many HTML tags allow script in their attributes. For example, the tag
> <img src="javascript:alert('hi')">
> is legal. If you want to accept HTML tags that are more complex than simple formatting tags, you must be sure that a malicious user cannot pass script to your application in the guise of an allowed HTML tag.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button1.Click
   Dim userinput As String = TextBox1.Text
   userinput = Server.HtmlEncode(userinput)
   ' Accepts <b>, </b>, <u>, </u>, case-insensitive
   userinput = userinput.Replace("&lt;b&gt;", "<b>")
   userinput = userinput.Replace("&lt;/b&gt;", "</b>")
   userinput = userinput.Replace("&lt;B&gt;", "<B>")
   userinput = userinput.Replace("&lt;/B&gt;", "</B>")
   userinput = userinput.Replace("&lt;u&gt;", "<u>")
   userinput = userinput.Replace("&lt;/u&gt;", "</u>")
   userinput = userinput.Replace("&lt;U&gt;", "<U>")
   userinput = userinput.Replace("&lt;/U&gt;", "</U>")
   Label1.Text = userinput
End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e)
{
    String userinput = TextBox1.Text;
    userinput = Server.HtmlEncode(userinput);
    // Accepts <b>, </b>, <u>, </u>, case-insensitive
    userinput = userinput.Replace("&lt;b&gt;", "<b>");
    userinput = userinput.Replace("&lt;/b&gt;", "</b>");
    userinput = userinput.Replace("&lt;B&gt;", "<B>");
    userinput = userinput.Replace("&lt;/B&gt;", "</B>");
    userinput = userinput.Replace("&lt;u&gt;", "<u>");
    userinput = userinput.Replace("&lt;/u&gt;", "</u>");
    userinput = userinput.Replace("&lt;U&gt;", "<U>");
    userinput = userinput.Replace("&lt;/U&gt;", "</U>");
    Label1.Text = userinput;
}
```

Scripting Exploits | Overview of Web Application Security Threats | Basic Security Practices for Web Applications | Security Portal

Displaying Safe Error Messages

When your application displays error messages, it should not give away information that a malicious user might find helpful in attacking your system. For example, if your application unsuccessfully tries to log into a database, it should not display an error message that includes the user name it is using.

There are a number of ways to control error messages:

- Configure the application not to show verbose error messages to remote (application) users. You can optionally redirect errors to an application page.
- Include error handling whenever practical and construct your own error messages. In your error handler, you can test to see if the user is local and react accordingly.
- Create a global error handler at the page or application level that catches all unhandled exceptions and routes them to a generic error page. That way, even if you did not anticipate a problem, at least users will not see an exception page.

To configure the application to turn off errors for remote users

- In the Web.config file for your application, make the following changes to the `customErrors` element:
  - Set the `mode` attribute to `RemoteOnly` (case sensitive). This configures the application to show detailed errors only to local users (you, the developer).
  - Optionally include a `defaultRedirect` attribute that points to an application error page.
  - Optionally include `<error>` elements that redirect specific errors to specific pages. For example, you can redirect standard 404 errors (page not found) to your own application page.

  The following example shows a typical `customErrors` block in the Web.config file.

```
<customErrors mode="RemoteOnly" defaultRedirect="AppErrors.aspx">
   <error statusCode="404" redirect="NoSuchPage.aspx"/>
   <error statusCode="403" redirect="NoAccessAllowed.aspx"/>
</customErrors>
```

To include error handling

1. Use try-catch-finally blocks around any statements that might generate errors.
2. Optionally, test for a local user with the Context object's UserHostAddress property and modify error handling accordingly. The value 127.0.0.1 is equivalent to "localhost" and indicates that the browser is on the same computer as the Web server.

   The following shows an example error-handling block. If an error occurs, a Session state variable is loaded with details about the message and the application then displays a page that can read the Session variable and display the error. (The error is deliberately written to provide no exploitable details to the user.) If the user is local, different error details are provided. In the **finally** block, an open resource is released.

```
' Visual Basic
Try
   SqlConnection1.Open()
   SqlDataAdapter1.Fill(Me.DsPubs1)
Catch ex As Exception
   If HttpContext.Current.Request.UserHostAddress = "127.0.0.1" Then
      Session("CurrentError") = ex.Message
    Else
      Session("CurrentError") = "Error processing page."
    End If
    Server.Transfer("ApplicationError.aspx")
Finally
       SqlConnection1.Close()
End Try

// C#
try
```

```
{
    sqlConnection1.Open();
    sqlDataAdapter1.Fill(dsCustomers1);
}
catch (Exception ex)
{
    if(HttpContext.Current.Request.UserHostAddress == "127.0.0.1")
    { Session["CurrentError"] = ex.Message; }
    else
    { Session["CurrentError"] = "Error processing page."; }
    Server.Transfer("ApplicationError.aspx");
}
finally
{
    this.sqlConnection1.Close();
}
```

You can also create an error handler that catches all unhandled exceptions at the page level or for the application as a whole.

To create global error handler

- To create a global handler in a page, create a handler for the Page_Error event. To create an application-wide error handler, in the Global.asax file, add code to the Application_Error method. These methods are called if an unhandled exception occurs anywhere in your page or application. You can get information about the most recent error from the HttpServerUtility.GetLastError method.

  Note If you have a global error handler, it takes precedence over error handling specified in the defaultRedirect attribute of the Web.config customErrors element.

  The following shows a sample handler that gets information about the current error, puts it into a Session variable, and calls a generic error-handling page that can extract and display the error information.

```
' Visual Basic
Sub Application_Error(ByVal sender As Object, ByVal e As EventArgs)
   Session("CurrentError") = "Global: " & Server.GetLastError.Message
   Server.Transfer("lasterr.aspx")
End Sub

// C#
protected void Application_Error(Object sender, EventArgs e)
{
    Session["CurrentError"] = "Global: " +
        Server.GetLastError().Message;
    Server.Transfer("lasterr.aspx");
}
```

Accessing SQL Server from a Web Application

When a Web application involves database access, it must provide credentials to SQL Server (that is, it must log in to SQL Server) just as any other user or process would. In a Web application, this can introduce complications. For example, if the Web application runs anonymously, there might not be credentials to pass to SQL Server.

There are a number of ways to design SQL Server access for your Web application. The strategy you choose depends on how your computers are configured and whether you are on an intranet. The simplest options are:

- Use Windows integrated security. This option passes the user's credentials to SQL Server. Because of delegation issues, this is practical primarily if SQL Server is on the same computer as IIS and your users must be on the same domain as the Web server computer. For details, see Accessing SQL Server Using Windows Integrated Security.
- Access the SQL Server as the local ASPNET or NETWORK SERVICE process (the default user identity for a Web application in your application). This option works well for anonymous access, but works only if SQL Server and the Web server are on the same computer. For details, see Accessing SQL Server as a Local User.
- Map the Web application process to a Windows domain user and then log into the database as that user. This works well for anonymous access if SQL Server and the Web server are on separate computers. For details, see Accessing SQL Server Using a Mapped Windows Domain User.
- Pass an explicit user name and password in a connection string. This option is practical if you can prompt the user for credentials, but can be less secure than other options. You can also choose it as an easier alternative to mapping to a Windows domain user. For details, see Accessing SQL Server with Explicit Credentials.

If you are familiar with other Windows features that help maintain the protection of users' information such as Kerberos, Active Directories, Passport, and so on, you can also take advantage of those to create database access. For more information, see Kerberos Authentication and Trust and Active Directory Security.

Accessing SQL Server Using Windows Integrated Security

If your application runs on a Windows-based intranet, you might be able to use Windows integrated security for database access. Integrated security requires:

- That SQL Server be running on the same computer as IIS.
- That all application be users on the same domain so that their credentials are available to the Web server. (That is, Windows integrated security is not practical for a public Web site.)

> **Note** If SQL Server and IIS are not on the same computer, use an alternative access method. For details, see Accessing SQL Server with Explicit Credentials and Accessing SQL Server Using a Mapped Windows Domain User.

To access SQL Server using Windows integrated security, you need to configure four different areas of your application:

- IIS
- The application configuration file (Web.config)
- Connection strings
- SQL Server itself

Configuring IIS

You need to configure your application in IIS to turn off anonymous access and turn on Windows authentication.

To configure IIS for Windows integrated security

1. In Windows, open the Internet Information Services administration tool.
   - In Windows 2000, this is available from the Start menu by pointing to Programs, then Administrative Tools, and then Internet Services Manager.
   - In Windows XP, this is available from Administrative Tools in the Control Panel.
2. Open the node for your server, and then open nodes until you find the node for your application, typically under Default Web Site.
3. Right-click your application and choose **Properties**.
4. In the **Directory Security** tab, click **Edit**.
5. In the **Authentication Methods** dialog box, clear the **Anonymous Access** box and make sure **Integrated Windows authentication** is checked.
6. Click **OK** to close all the dialog boxes.

Configuring the Web.config File

In the application configuration file (Web.config), you establish the authentication mode that your application uses and establish that the application will impersonate the user's credentials — that is, that it will run as that user.

To configure Web.config to allow Windows integrated security

- Open the Web.config file for your application and add the following elements to it:

  ```
  <authentication mode="Windows" />
  <identity impersonate="true"/>
  ```

  The <authentication> element might already be there.

  > **Note** Elements in Web.config are case sensitive.

Creating Connection Strings

When you create a connection string to access SQL Server, you must include attributes that tell SQL Server that you are using Windows integrated security.

To configure connection strings for Windows integrated security

- In any connection string for SQL Server, include the attribute `Trusted_Connection=Yes` and remove the username and password attributes.

  The following shows a typical connection string configured for Windows integrated security:

  ```
  "workstation id=WebServer1;packet size=4096;
  Trusted_Connection=Yes;data source=mySqlServers";
  persist security info=False;initial catalog=northwind"
  ```

Configuring SQL Server

You must set up SQL Server to recognize the users who will be accessing it.

To configure SQL Server for Windows integrated security

1. From the Windows **Start** menu, choose **Microsoft SQL Server**, and then choose **Enterprise Manager**.
2. Open the node for the server and expand the node for the database you want to give users permissions for.
3. Right-click the **Users** node and choose **New Database User**.
4. In the **Database User Properties** dialog box, enter *domain\username* in the **Login name** box, and then click **OK**. Alternatively, configure the SQL Server to allow all domain users to access the database.

Accessing SQL Server Using a Mapped Windows Domain User

By default, ASP.NET applications run in the context of the local user called ASPNET in Windows 2000 and Windows XP or NETWORK SERVICE in Windows Server 2003. These user accounts have limited permissions. However, the ASPNET or NETWORK SERVICE user is local to the Web server computer and is therefore not recognized as a user on remote computers. To get around this limitation, you can have your application run in the context of a Windows domain user that is recognized on both the Web server computer and on the SQL Server computer.

Mapping your application process to a Windows domain user requires that you configure the following processes:

- **The Web server computer** You must be sure that the Windows domain user you specify has sufficient privileges (but no more) to run a Web application.
- **Your application** You need to configure the Web.config file to specify that ASP.NET use integrated security, which allows ASP.NET to recognized the mapped user name.

  Note For information on the machine.config and Web.config files, see ASP.NET Configuration.

- **Connection string** When you create connection strings for connection objects in your application, you need to specify that they will use integrated security.
- **SQL Server** You need to add the specified domain user as a SQL Server login user.

Configuring Users on the Web Server Computer

To set user permissions for the Windows domain user

- Using Windows administrative tools on the Web server computer, make sure that the mapped Windows domain user has necessary privileges. For details, see ASP.NET Required Access Control Lists (ACLs).

Mapping to the Windows User and Enabling Impersonation

After establishing the correct permissions for the ASPNET or NETWORK SERVICE user account and for the user to map to, you configure the application to impersonate that user.

To configure your Web application for integrated security

- Open the Web.config file for your application and add the following elements:

  ```
  <authentication mode="Windows" />
  <identity impersonate="true" userName="domain\username" password="password"/>
  ```

  The `<authentication>` element might already be there.

  Note Elements in Web.config are case sensitive.

Using Windows Security in the Connection String

Finally, when you create connection strings for database access, configure them to use Windows integrated security.

To use Windows security in the connection string

- When you create a connection string for your application, do not include a user name and password. Instead, set the connection string's Integrated Security attribute to SSPI.

  The following example shows a connection string that includes the appropriate attributes:

  ```
  data source=myserver;initial catalog=northwind;Integrated Security=SSPI
  ```

To configure SQL Server for integrated security

1. From the Windows **Start** menu, choose **Microsoft SQL Server**, and then choose **Enterprise Manager**.
2. Open the node for the server and expand the node for the database you want to give users permissions for.
3. Right-click the **Users** node and choose **New Database User**.
4. In the **Database User Properties** dialog box, enter *domain\username* in the **Login name** box, and then click **OK**.

Accessing SQL Server as a Local User

When an ASP.NET application runs, by default it runs in the context of a special local user called ASPNET (in Windows 2000 and Windows XP) or NETWORK SERVICE (in Windows Server 2003). This user account has just enough permissions on the Web server computer to allow the application to run.

If SQL Server and the Web server are on the same computer, you can define the ASPNET or NETWORK SERVICE user as a user on the SQL Server.

The advantages of this method are that it is secure, because the Web application runs within a limited security context. Using a single user name with SQL Server is also efficient because it enables SQL Server to take advantage of connection pooling, enhancing the scalability of the application.

To give the ASPNET or NETWORK SERVICE user SQL Server permissions

1. From the Windows **Start** menu, choose **Microsoft SQL Server**, and then choose **Enterprise Manager**.
2. Open the node for the server and expand the node for the database you want to give users permissions for.
3. Right-click the **Users** node and choose **New Database User**.
4. In the **Database User Properties** dialog box, enter *computername*\ASPNET in the **Login name** box, and then click **OK**.

Accessing SQL Server from a Web Application | Database Security | Access Permissions for Web Applications | Security Portal

Accessing SQL Server with Explicit Credentials

A reliable way to connect to SQL Server is to pass a user name and password in the connection string. You can use this strategy in different ways:

- Prompt the user for the user name and password.
- Use a predetermined user name and password.

> **Security Note** Using a connection string to access SQL Server is not as secure as using integrated security. Use a connection string with explicit credentials only if it is impractical in your application to use integrated security.

Prompting for Credentials

You can prompt for a user name and password (for example, using Forms authentication), and then pass credentials to SQL Server in the connection string. Prompting for credentials has some disadvantages. It requires that each user be recognized separately by SQL Server. It also is inefficient for connection pooling and thus can limit scalability. For an example of Forms authentication, see Simple Forms Authentication.

> **Security Note** Prompting the user for a username and password in your application is a potential security threat. Credential information must be transferred from the browser to your server, and ordinary HTTP transfers are unencrypted. For best security when prompting users to provide credentials in your application, you should use secure sockets layer (SSL), which encrypts information before sending it from the browser to the server. For details on how to implement SSL, see Microsoft Knowledge Base article Q307267, "HOW TO: Secure XML Web Services with Secure Socket Layer in Windows 2000.

To pass an explicit user name in the connection string dynamically

- After getting the user's name and password, concatenate them into the connection string in code, and then assign them to the ConnectionString property of a connection object.

  > **Security Note** You should be sure that the user name and password do not contain malicious content. The example below illustrates one method to do so. For more information, see Scripting Exploits.

  The following example shows a dynamically created connection string. The user name and password are assumed to be available in text boxes. The user input is filtered with a function that makes sure that it contains only pre-determined characters.

  > **Tip** If you are familiar with using regular expressions, you can create a more efficient version of this filter. For details, see Regular Expression Classes.

```
' Visual Basic
Private Function ValidateInput(ByVal validchars As String, _
        ByVal userinput As String) As Boolean
    Dim c As Char
    For Each c In userinput
        If validchars.IndexOf(c) < 0 Then
            Return False
        End If
    Next
    Return True
End Function

Private Sub OpenDatabase()
    Dim vChars As String = _
        "ABCDEFGHIJKLMNOPQRSTUVWXYZabcdefghijklmnopqrstuvwxyz*&%$#!"
    Dim userid As String
    Dim password As String
    If ValidateInput(vChars, UserName.Text) Then
        userid = UserName.Text
    Else
```

```
        Throw New System.Exception("Invalid user name.")
    End If
    If ValidateInput(vChars, PasswordText.Text) Then
        password = PasswordText.Text
    Else
        Throw New System.Exception("Invalid password.")
    End If
    Dim connectionString As String
    connectionString =  "data source=myserver"
    connectionString &= ";initial catalog=northwind"
    connectionString &= ";user id=" & userid
    connectionString &= ";password=" & password
    SqlConnection1.ConnectionString = connectionString
    SqlConnection1.Open()
    ' Further code to work with the database
End Sub

// C#
private Boolean ValidateInput(String validchars, String userinput)
{
    foreach(Char c in userinput)
    {
        if(validchars.IndexOf(c) < 0)
        {
            return false;
        }
    }
    return true;
}

private void OpenDatabase()
{
    String vChars =
       "ABCDEFGHIJKLMNOPQRSTUVWXYZabcdefghijklmnopqrstuvwxyz*&%$#!";
    String userid;
    String password;
    if(ValidateInput(vChars, UserName.Text))
    {
        userid = UserName.Text;
    }
    else
    {
        throw new System.Exception("Invalid user name.");
    }
    if(ValidateInput(vChars, PasswordText.Text))
    {
        password = PasswordText.Text;
    }
    else
    {
        throw new System.Exception("Invalid password.");
    }
    String connectionString;
    connectionString =  "data source=myserver";
    connectionString += ";initial catalog=northwind";
    connectionString += ";user id=" + userid;
            connectionString += ";password=" + password;
    sqlConnection1.ConnectionString = connectionString;
    sqlConnection1.Open();
```

```
    // Further code to work with the database
}
```

Using Predetermined Credentials

If it is not practical to prompt for credentials, you can use a predetermined user name and password. The recommended method is to store the predetermined user name and password on the server, and then read it and add it to the connection string at run time. An advantage of this technique is that your application can access the database using different credentials under different circumstances, depending on what it needs to do in the database.

> **Security Note** Never hard-code credentials as strings into programs in your application. Anyone who can get access to the code file, even the compiled code, will be able to get at the credentials.
>
> **Security Note** Always give a predetermined user name the minimal access privileges to a resource. Never use "sa" or any other administrative-level user name. Always use passwords.

You can store credentials in a variety of places. Two options are:

- In the Web.config file. This makes it easy to deploy the configuration information along with the application. Although the configuration file is stored in the same directory as the ASP.NET application, ASP.NET prevents clients from directly accessing files with a .config extension. For additional security, you can set the configuration file's NTFS file system permissions and encrypt the connection string within the file.
- In the Windows registry, as a custom subkey. The credentials are not stored in a Web-accessible directory, which decreases the potential visibility of the string. However, this approach complicates deployment, since installing the application requires changes to the target computer's registry. For additional security, you can use access control lists (ACLs) to restrict access to the registry subkey and encrypt the connection string within the subkey.

> **Note** For further information about storing database credentials, see Database Security.

If you do store credentials as part of an application, you should make an attempt to protect them with encryption. One possibility is to use the Data Protection API (DPAPI). For details, see the MSDN technical article Windows Data Protection.

To store credentials in Web.config

1. In the Web.config file, create a new `<add>` key in the `<appSettings>` element. The `<appSettings>` element must appear as a child of the `<configuration>` element. For details, see Configuration Sections Schema.

   The following example illustrates an <add> key that contains a user name and password, labeled "mappedname" and "mappedkey."

   > **Tip** It is a good idea to avoid using the strings "password" and "user name" (or "username") in your application, so that malicious users searching for those terms will not find them.

   ```
   <appSettings>
      <add key="mappedname" value="MyWebAppUser"/>
      <add key="mappedkey" value="Aje$31"/>
   </appSettings>
   ```

2. In your application, read the credentials from the static AppSettings property of the System.Configuration.ConfigurationSettings class.

   The following example shows how you can read credentials at run time and concatenate them into a connection string:

   ```
   ' Visual Basic
   Dim connectionString As String
   Dim user As String = System.Configuration.ConfigurationSettings. _
       AppSettings("mappedname")
   Dim pass As String = System.Configuration.ConfigurationSettings. _
       AppSettings("mappedkey")
   connectionString =  "data source=myserver;initial catalog=northwind"
   connectionString &= ";user id=" & user
   connectionString &= ";password=" & pass
   ```

```
SqlConnection1.ConnectionString = connectionString

// C#
String connectionString;
String user = System.Configuration.ConfigurationSettings.
    AppSettings["mappedname"];
String pass = System.Configuration.ConfigurationSettings.
    AppSettings["mappedkey"];
connectionString =  "data source=myserver;initial catalog=northwind";
connectionString += ";user id=" + user;
connectionString += ";password=" + pass;
sqlConnection1.ConnectionString = connectionString;
```

To store credentials in the registry

1. Add new subkeys to the **SOFTWARE** key in the **HKEY_LOCAL_MACHINE** hive.
2. In your application, access the subkey using the OpenSubKey method of the Registry.LocalMachine object.

   Note You must import the **System** and **Microsoft.Win32** namespaces in order to use the **Registry** class.

   The following example illustrates how to get a user name and password (stored as string values called "mappedname" and "mappedkey") from the subkey "Connection":

```
' Visual Basic
Dim user, pass, connectionString As String
user = Microsoft.Win32.Registry.LocalMachine.OpenSubKey( _
   "Software\Connection").GetValue("mappedname").ToString()
pass = Microsoft.Win32.Registry.LocalMachine.OpenSubKey( _
   "Software\Connection").GetValue("mappedkey").ToString()
connectionString = "data source=myserver;initial catalog=northwind"
connectionString &= ";user id=" & user
connectionString &= ";password=" & pass
SqlConnection1.ConnectionString = connectionString

// C#
String user, pass, connectionString;
user = Microsoft.Win32.Registry.LocalMachine.
    OpenSubKey("Software\\Connection").
    GetValue("mappedname").ToString();
pass = Microsoft.Win32.Registry.LocalMachine.
    OpenSubKey("Software\\Connection").
    GetValue("mappedkey").ToString();
connectionString = "data source=myserver;initial catalog=northwind";
connectionString += ";user id=" + user;
connectionString += ";password=" + pass;
sqlConnection1.ConnectionString = connectionString;
```

Introduction to Web Application Debugging

The ASP.NET page framework provides extensive support for debugging Web applications. However, because Web applications are distributed, there are some special issues associated with debugging them.

In general, you debug Web applications the same way you do other types of Visual Studio applications. You can set breakpoints, start the debugger, break into code, examine variables, and perform all the functions associated with the Visual Studio debugger. For details, see Using the Debugger.

You can debug managed and unmanaged objects, as well as all supported common language runtime languages and script languages. For more information, see Debugging Managed Code. In addition, the ASP.NET page framework provides a trace mode that enables you to insert instrumentation messages into your forms. For details, see Introduction to Instrumentation and Tracing.

Debugger Configuration

Web application debugging requires certain components on the computer where debugging is to happen and requires that you have adequate permissions.

Local Computer Configuration

If you are running Web applications locally on your computer — that is, the Web server is on your computer — then the computer has the correct components automatically.

You must still make sure that you have adequate permissions to debug. When you install Visual Studio or Visual Studio server components on a computer, it creates a Windows group called Debugger Users. Any developer who wants to be able to debug on that computer must be a member of that group. (Having a special group for debugger users allows the server administrator to control who has debugging privileges separately from users who have other permissions for that server.)

If you installed Visual Studio, then your user name is added to the Debugger Users group. Any other users who want to debug — other users, or you logged in under a different profile — must be manually added to the Debugger Users group.

> **Security Note** Membership in the Debugger Users group effectively grants users administrative-level privileges. Do not make anyone a member of this group who should not have this level of privilege.

Remote Computer Configuration

If the Web server is on another computer (a remote server), you must ensure that the computer is configured properly. This involves:

- Making sure that DCOM is installed on both your computer and on the server. Windows 2000 normally has DCOM installed already, so there is usually no action required on your part.
- Installing Visual Studio server-side components on the remote computer. You can do this by running the Visual Studio installation process on the remote computer and selecting the option for server components.
- Adding user permissions by adding user names to the Debugger Users group.
- Ensuring that any debugger users have permissions to attach to a Web server process. This means that server processes must either run as the user (impersonation) or that users who want to debug must have administrative privileges on the Web server. (Giving users administrative privileges on the server might not be in keeping with your security policies.) You can control ASP.NET impersonation using the <identity> setting of the Web.config file for your application. For details, see <identity> Element.

For details about configuring for remote debugging, see Debugging Web Applications on a Remote Server.

Whether you are running locally or on a remote computer, you must be sure that debugging is enabled for your Web application specifically. This is done in the <compilation> element of the Web.config file that is part of your Web application project. This setting instructs the compiler to insert debugging symbols into the application's compiled code so that you can use the debugger with it. For details, see Debug Mode in ASP.NET Applications.

Debugging Client Script

Client script runs within the browser, separately from the code in your Web application, which runs on the server. You can use the Visual Studio debugger to debug client script. The debugger does not allow you to follow execution from server code to client script; however, it does support most other debugging functionality for client script.

You can debug client script in various ways. From within Visual Studio, you can use debugger commands to attach to the browser process (Iexplore.exe) and break into the script. From there, you can use the debugger as you would for any other code.

For details, see Debugging Client-Side Scripts.

Web Forms Pages

Web Forms is an ASP.NET feature that you can use to create the user interface for your Web applications. Web Forms pages offer you a powerful and straightforward programming model that uses familiar rapid application development (RAD) techniques to build sophisticated Web-enabled user interfaces. The following topics provide background information that you will find useful in learning to work with Web Forms pages.

In This Section

Introduction to Web Forms Pages
Presents a high-level overview of Web Forms pages and describes why Web Forms pages solve problems unique to Web application development.
Creating and Managing Web Forms Pages
Provides instructions on creating and managing Web Forms pages.
Programming Web Forms
Provides information on the specific aspects of programming in a Web Forms environment.
Data Access in Web Forms Pages
Provides a summary of ASP.NET data binding technology in Web Forms pages.

Introduction to Web Forms Pages

You can use Web Forms pages to create programmable Web pages that serve as the user interface for your Web application. A Web Forms page presents information to the user in any browser or client device and implements application logic using server-side code. Web Forms page output may contain almost any HTTP-capable language, including HTML, XML, WML, and ECMAScript (JScript, JavaScript).

Web Forms pages are:

- Based on Microsoft ASP.NET technology in which code that runs on the server dynamically generates Web page output to the browser or client device. For details about ASP.NET, see ASP.NET Technology Backgrounder.
- Compatible with any browser or mobile device. A Web Forms page automatically renders the correct browser-compliant HTML for features such as styles, layout, and so on. Alternatively, you can design your Web Forms pages to run on a specific browser such as Microsoft Internet Explorer 5 and take advantage of the features of a rich browser client.
- Compatible with any language supported by the .NET common language runtime, including Microsoft Visual Basic, Microsoft Visual C#, and Microsoft JScript .NET.
- Built on the Microsoft .NET Framework. This provides all the benefits of the framework, including a managed environment, type safety, and inheritance.
- Supported in Visual Studio with powerful rapid application development (RAD) tools for designing and programming your forms.
- Extensible using controls that provide RAD capability for Web development, allowing you to create rich user interfaces quickly.
- Flexible because you can add user-created and third party controls to them.

Components of Web Forms

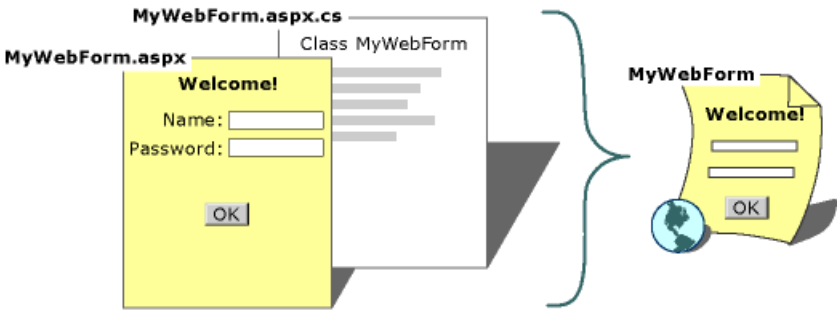
In Web Forms pages, the user interface programming is divided into two distinct pieces: the visual component and the logic. If you have worked with tools like Visual Basic and Visual C++ in the past, you will recognize this division between the visible portion of a form and the code behind the form that interacts with it.

The visual element is referred to as the Web Forms *page*. The page consists of a file containing static HTML, or ASP.NET server controls, or both simultaneously.

The Web Forms page works as a container for the static text and controls you want to display. Using the Visual Studio Web Forms Designer plus ASP.NET server controls, you can design the form as you would in any Visual Studio application. For more information, see Controls You Can Use on Web Forms Pages.

The logic for the Web Forms page consists of code that you create to interact with the form. The programming logic resides in a separate file from the user interface file. This file is referred to as the "code-behind" file and has an ".aspx.vb" or ".aspx.cs" extension. The logic written in the code-behind file can be written in Visual Basic or Visual C#.

Web Forms File Structure



Both files together make up MyWebForm.

The code-behind class files for all Web Forms pages in a project are compiled into the project dynamic-link library (.dll) file. The .aspx page file is also compiled, but somewhat differently. The first time a user browses to the .aspx page, ASP.NET automatically generates a .NET class file that represents the page, and compiles it to a second .dll file. The generated class for the .aspx page inherits from the code-behind class that was compiled into the project .dll file. When a user requests the Web page URL, the .dll files run on the server and dynamically produce the HTML output for your page. For more information, see Web Forms Page Processing.

For more information about how Web Forms pages are constructed, see Web Forms Code Model.

What Web Forms Pages Help You Accomplish

Web application programming presents challenges that do not typically arise when programming traditional client-based applications. Among the challenges are:

- **Implementing a rich Web user interface.** A user interface with a complex layout, a large amount of dynamic content, and full-featured user-interactive objects can be difficult and tedious to design and implement using basic HTML facilities. It is particularly difficult to create a rich user interface for applications likely to run on many different browser and client device platforms.
- **Separation of client and server.** In a Web application, the client (browser) and server are different programs often running on different computers (and even on different operating systems). Consequently, the two halves of the application share very little information; they can communicate, but typically exchange only small chunks of simple information.
- **Stateless execution.** When a Web server receives a request for a page, it finds the page, processes it, sends it to the browser, and then, effectively, discards all page information. If the user requests the same page again, the server repeats the entire sequence, reprocessing the page from scratch. Put another way, a server has no memory of pages that it has processed. Therefore, if an application needs to maintain information about a page, this becomes a problem that has to be solved in application code.
- **Unknown client capabilities.** In many cases, Web applications are accessible to many users using different browsers. Browsers have different capabilities, making it difficult to create an application that will run equally well on all of them.
- **Complications with data access.** Reading from and writing to a data source in a traditional Web applications can be complicated and resource-intensive.
- **Complications with scalability.** In many cases Web applications designed with existing methods fail to meet scalability goals due to the lack of compatibility between the various components of the application. This is often the single failure point for applications under a heavy growth cycle.

Meeting these challenges for Web applications can require substantial time and effort. Web Forms pages and the ASP.NET page framework address these challenges in the following ways:

- **Intuitive, consistent object model.** The ASP.NET page framework presents an object model that allows you to think of your forms as a unit, not as separate client and server pieces. In this model, you can program the form in a more intuitive way than in traditional Web applications, including the ability to set properties for form elements and respond to events. In addition, ASP.NET server controls are an abstraction from the physical contents of an HTML page and from the direct interaction between browser and server. In general, you can use server controls the way you might work with controls in a client application and not have to think about how to create the HTML to present and process the controls and their contents.
- **Event-driven programming model.** Web Forms pages bring to Web applications the familiar model of writing event handlers for events that occur on either the client or server. The ASP.NET page framework abstracts this model in such a way that the underlying mechanism of capturing an event on the client, transmitting it to the server, and calling the appropriate method is all automatic and invisible to the implementer. The result is a clear, easily written code structure that supports event-driven development.
- **Intuitive state management.** The ASP.NET page framework automatically handles the task of maintaining the state of your form and its controls, and it provides you with explicit ways to maintain the state of application-specific information. This is accomplished without heavy use of server resources and can be implemented with or without sending cookies to the browser.
- **Browser-independent applications.** The ASP.NET page framework provides for creating all application logic on the server, eliminating the need to explicitly code for differences in browsers. However, it still allows you to automatically take advantage of browser-specific features by writing client-side code to provide improved performance and a richer client experience.
- **.NET Framework common language runtime support.** The ASP.NET page framework is a technology of ASP.NET. ASP.NET is built on the .NET Framework, so the entire framework is available to any ASP.NET application. Your applications can be authored in any language compatible with the runtime, including Microsoft Visual Basic, Visual C#, and JScript .NET. In addition, data access is simplified using the data access infrastructure provided by the .NET Framework, including ADO.NET.
- **.NET Framework scalable server performance.** The ASP.NET page framework allows you to scale your Web application from one computer with a single processor to a multi-computer "Web farm" cleanly and without complicated changes to the application's logic.

Walkthrough: Creating a Basic Web Forms Page | Migrating to Web Forms | Walkthrough: Creating an Accessible Web Application

Web Forms Code Model

A Web Forms page consists of two parts: visual elements (HTML, server controls, and static text) and the page's programming logic. Visual Studio stores each of these components in a separate file. The visual elements are created in an .aspx, and the code is in a separate class file, called the code-behind class file (.aspx.vb or .aspx.cs).

It is also possible to create the visual elements and code in the same file, which is sometimes called a "single-file" Web Forms page. This style of Web Forms page has limited support in Visual Studio. For details, see "Single-File Web Forms Pages" below.

> **Note** Visual Studio does not support cross-language compiling in Web Forms pages and projects. This means it is not possible to include a Visual C# Web Forms page in a Visual Basic Web project, and vice versa.

The ASP.NET Page Class

Although a Web Forms page consists of two separate files, they form a single unit when your application is run. The code-behind class files for all Web Forms in a project are compiled into the dynamic-link library (.dll) file produced by the project. The Web Forms .aspx page file is also compiled, but somewhat differently. The first time a user browses to the .aspx page, ASP.NET automatically generates a .NET class file that represents the page and compiles it to a second .dll file. The generated class for the .aspx page inherits from the code-behind class that was compiled into the project .dll file.

This single .dll file is run at the server whenever the Web Forms page is requested. At run time, this .dll file processes the incoming request and responds by dynamically creating output and sending it back to the browser or client device.

If the page contains server controls, as is typical, the derived page class acts as a container for the controls. Instances of the controls are created at run time and likewise render output for the browser or client device.

For developers familiar with Active Server Pages (ASP), the ASP.NET page framework model represents something new. The ASP model is one of HTML extended with script code. The ASP page consists of script code, such as ECMAScript (JScript, JavaScript) or VBScript, coexisting with static HTML within the same file. The ASP parser reads the page, interprets it, and runs only the script code to get output results. ASP then merges the output of the script code with the static HTML output found in the page before sending the output back to the browser or client device.

In the ASP.NET **Page** class model, the entire Web Forms page is, in effect, an executable program that generates output to be sent back to the browser or client device. In this model, the page goes through a series of processing stages similar to those of other components — initialize, process, and dispose — with two differences:

- The page class performs these steps each time the page is called. The page is initialized, processed, and disposed of every time a round trip to the server occurs.
- The page class has a unique stage —render— that occurs toward the end of the page life cycle, during which output is generated. For more information, see Control Execution Lifecycle.

> **Note** For efficiency, the information required to recreate the page may be cached, but this action is independent of its life cycle.

Deriving from the Page Class

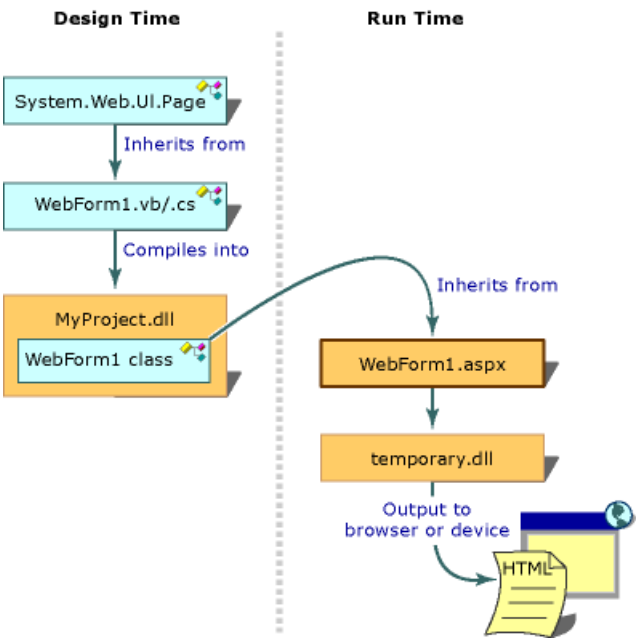
When Visual Studio creates the page and class files for a Web Forms page, it generates code that inherits from the base **Page** class. For example, if you create a new Web Forms page and name it WebPage1, a new class named WebPage1 is derived from **System.Web.UI.Page**.

Depending on whether you have chosen Visual Basic or Visual C# for your development, Visual Studio generates either of the following lines of code:

```
' Visual Basic
Public Class WebForm1
    Inherits System.Web.UI.Page
// C#
public class WebForm1 : System.Web.UI.Page
```

The .aspx page file in turn inherits from the derived WebPage1 class. The relationship of the base **Page** class, the derived class file, and the .aspx file is illustrated in the following diagram.

Web Forms Page Structure and the Page Base Class



Because the .aspx file is compiled dynamically when a user browses the page, its relationship to the class file is established with script directives at the top of the page. In Visual Studio, the relationship between .aspx files and class files is created and maintained automatically, even if you rename the Web Forms page. Specifically, the **Inherits** attribute of the **@ Page** directive is used to specify the class file from which the .aspx file is derived. A typical directive looks like this:

```
<%@ Page Language="vb" AutoEventWireup="false" Codebehind="WebForm1.aspx.vb" Inherits="WebApp
lication1.WebForm1"%>
```

The Codebehind, Inherits, and Src Attributes

In Web Forms that use code-behind files, the @ Page directive (or **@ Control** in user control files) contains attributes that specify the relationship of the .aspx file and its code-behind file. These attribute are:

- **Codebehind** In Visual Studio, this attribute references the name of a file that contains the class for the page. For example, if you create a Web Forms page in Visual Studio called `WebForm1`, the **Codebehind** attribute will point to `WebForm1.aspx.vb` or `WebForm1.aspx.cs`. This attribute is used only by the Visual Studio Web Forms Designer. It tells the designer where to find the page class so that the designer can create an instance of it for you to work with. The attribute is not used at run time.
- **Inherits** Identifies the class from which the page derives. In Visual Studio, this points to a class in the project assembly (.dll), as shown in the diagram above.

The code-behind model illustrated above is the model used by Visual Studio. The ASP.NET Framework supports a slightly different code-behind model for Web Forms pages. In the ASP.NET code-behind model, the visual elements are in an .aspx file and the code is in a separate code-only file, as in Visual Studio. However, there is no project, and the code is not pre-compiled. Instead, the code in the .vb or .cs file is compiled at run time, when the page is first requested by a user.

The inheritance model works as illustrated above, with the difference that the Web Forms class (WebForm1 class in the diagram) is not part of a project assembly. Instead, each page is a separate assembly. There is no difference in how your code runs in the two models.

In the ASP.NET code-behind model, there is no **Codebehind** page attribute, since that attribute is unique to Visual Studio. To tie the .aspx file to its corresponding code, the page directive contains a **Src** attribute, which references the file containing the source code for the file.

The **Src** attribute is not supported in Visual Studio. If you import a Web Forms page into Visual Studio that contains the **Src** attribute, the designer will raise an error. For details, see The file could not be loaded into the Web Forms designer.

Single-File Web Forms Pages

In addition to pages that are made up of an .aspx file and a separate class file, the ASP.NET architecture supports a "single-file" model in which the UI elements and code are in the same file. Single-file Web Forms pages are functionally very similar to pages consisting of two files. For example, you use the same controls on both types of pages. Users still request pages using the same .aspx extension for the file name, and the page is still run using server-side code and it streams HTML to the client. A single-file

page has the advantage that it can be easier to deploy.

There are a few differences in the way single-file pages are processed:

- The code for the page is not compiled into a separate class that the .aspx file then derives from. Instead, the .aspx file simply derives from the **Page** class.
- When the page is deployed, the source code is deployed along with the Web Forms page, since it is physically in the .aspx file. (The user does not see the code — only the results rendered when the page runs are sent to the user.)

You can work with single-file Web Forms pages in Visual Studio, but because Visual Studio is oriented toward the two-file, code-behind model, there is more limited support for single-file pages. Differences include:

- You cannot directly create a single-file Web Forms page in Visual Studio. When you create a new page, by default Visual Studio creates a separate .aspx file and class file. To create a single-file page, you must initially create it as a text file and then change its extension to .aspx.
- You cannot add non-visual components to the page (such as data components) by dragging them from the Toolbox, because the Web Forms Designer will not persist them in the page. Instead, you should add such components in code.
- You write code in HTML view, not in the Code Editor.
- When you are writing code, Intellisense is not supported — you do not get syntax checking or statement completion, tabbing, or code formatting.
- You must bind events to event handlers manually. For single-file Web Forms pages, Visual Studio does not support double-clicking to create the handler for a control's default event, nor the drop-down lists of classes and events in the Code Editor.
- Some debugging features, such as the ability to see a variable value by pointing the mouse at it, are not supported.
- Because the code in the page is not compiled into the project assembly, compile-time errors are not caught until the page runs.

For more information about single-file Web Forms pages, see Working with Single-File Web Forms Pages in Visual Studio .NET.

Introduction to Web Forms Pages | Web Forms Page Processing | Compilation and Deployment of Web Projects

Web Forms Page Processing

In general, the life cycle for a Web Forms page is similar to that of any Web process that runs on the server. Certain characteristics of Web processing — information passed via HTTP protocol, the stateless nature of Web pages, and so on — apply to Web Forms pages just as they do to most Web applications.

However, the ASP.NET page framework performs many Web application services for you. For example, the ASP.NET page framework captures information posted with the Web Forms page, extracts the relevant values, and makes the information accessible via object properties.

It is important to understand the sequence of events that occurs when a Web Forms page is processed. This knowledge will help you program your Web Forms pages and Web applications more effectively.

The Life Cycle of a Web Forms Page

You might find it helpful to understand some fundamental characteristics of how Web Forms pages work in Web applications before you examine the details of what goes on inside a page when it is processed.

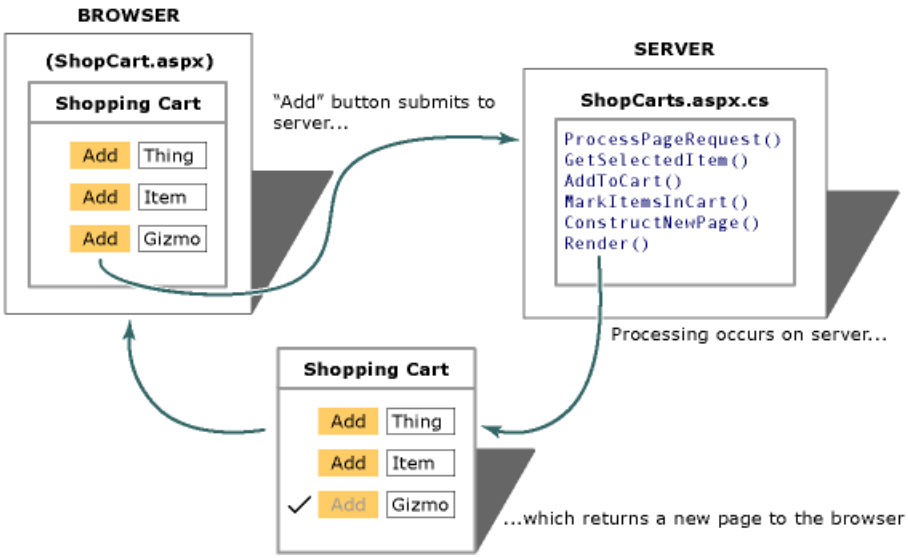
Round Trips

One of the most important things to understand is the division of labor in a Web Forms page. The browser presents the user with a form, and the user interacts with the form, causing the form to post back to the server. However, since all processing that interacts with server components must occur on the server, this means that for each action that requires processing, the form must be posted to the server, processed, and returned to the browser. This sequence of events is referred to as a *round trip*.

> **Note** You can create client script in Web Forms, which is useful for user input validation and for some types of UI programming. Client script does not interact with server components.

Imagine a business scenario: A user enters an order and you want to confirm sufficient inventory for the order, so your application posts the page to the server at an appropriate point in the user's order-entry process. A server process examines the order, performs an inventory lookup, perhaps takes some action defined in business logic (such as modifying the page to indicate an error), and then returns the page to the browser for the user to continue.

Round Trip



In Web Forms, most user actions — such as clicking a button — result in a round trip. For that reason, the events available in ASP.NET server controls are usually limited to click-type events. Most server controls expose a click event, one that requires an explicit user gesture.

By the same token, server controls do not expose high-frequency events such as **onmouseover**, because each time such an event is raised, another round trip to the server would occur, which would considerably affect response time in the form.

Recreating the Page (View State and State Management)

In any Web scenario, pages are recreated with every round trip. As soon as the server finishes processing and sending the page to the browser, it discards the page information. By freeing server resources after each request, a Web application can scale to support hundreds or thousands of simultaneous users. The next time the page is posted, the server starts over in creating and

processing it, and for this reason, Web pages are said to be *stateless* — the values of a page's variables and controls are not preserved on the server.

> **Note** The server can be configured to cache page information to optimize the pages, but for purposes of application programming, it is clearest to think of them as being disposed of as soon as the server has finished processing them.

In a traditional Web application, the only information that the server has about a form is the information that the user has added to the controls on the form, because that information is sent to the server when the form is posted. Other information, such as variable values and property settings, is discarded.

ASP.NET works around these limitations in the following ways:

- It saves page and control properties between round trips. This is referred to as saving the view state of the control.
- It provides state management facilities so you can save your own variable and application-specific or session-specific information between round trips.
- It can detect when a form is requested for the first time versus when the form is posted, which allows you to program accordingly. You may want a different behavior during a page postback versus an initial request.

Benefits of an Event-Driven Model versus a Linear Processing Model

If you have experience using Active Server Pages (ASP), you recognize that ASP is a linear processing model. An ASP page is processed in a top-to-bottom sequence. Each line of ASP code and static HTML is processed in sequence as it appears in the file. User actions cause the page to be posted to the server in a round trip. Since this action causes a round trip, the server must recreate the page. After the page is recreated, it is processed in the same top-to-bottom sequence as before, and therefore the page is not exhibiting truly event-driven behavior. To create an event-driven experience, you need to explicitly design it. In addition, you have to explicitly maintain page and control state at the most basic level. This model limits the richness of the user interfaces that can be assembled, and it increases the complexity of the code needed to support it.

In comparison, an event-driven model, as in a traditional Visual Basic application, contains programmable elements that are initialized and displayed on the form. Users interact with the elements, which cause events to be raised that in turn call event handlers. This model supports true event-driven behavior, which, by design, greatly extends the richness of the user interfaces that can be assembled, and it reduces the complexity of the code needed to support it.

ASP.NET replaces the linear processing model of ASP by emulating the behavior of an event-driven model. The ASP.NET page framework is provided to implicitly make the associations of an event to an event handler for you. Using the page framework allows you to easily create a user interface that reacts to user actions. For details on creating and using events and event handlers, see Server Event Handling in Web Forms Pages.

In addition, this same framework eases the implementation of page and control state management. For more information on state management, see Web Forms State Management.

For example, ASP.NET allows you to set up event handlers in server code for events that are passed from the browser. Assume the user is interacting with a Web Forms page that contains one button server control. The user clicks the button control and an event is raised that is transmitted via an HTTP post to the server where the ASP.NET page framework interprets the posted information and associates the raised event with an appropriate event handler. This event handler can be a default handler supplied by ASP.NET or it can be your custom implementation. The framework automatically calls the appropriate event handler for the button as part of the framework's normal processing. As a result, you no longer need to explicitly design event-like behavior into a linear processing model. For more information on Web Forms event handling, see ASP.NET Server Control Event Model.

Stages in Web Forms Processing

The ASP.NET page framework processes Web Forms pages in distinct stages. During each stage of Web Forms processing, events may be raised, and any event handler that corresponds to the event runs. These methods provide you with entry points — hooks — that allow you to update the contents of the Web Forms page.

The table below lists the most common stages of page processing, the events raised when they occur, and typical uses at each stage. These stages are repeated each time the form is requested or posted. The Page.IsPostBack property allows you to test whether the page is being processed for the first time.

> **Note** There are several more stages of Web Forms page processing than are listed in the following table. However, they are not used for most page processing scenarios. Instead, they are primarily used by server controls on the Web Forms page to initialize and render themselves. If you intend to write your own ASP.NET server controls, you need to understand more about these stages. For details about the complete set of page processing stages, see Developing ASP.NET Server Controls.

Stage	Meaning	Typical uses
ASP.NET Page Framework Initialization	The page's **Page_Init** event is raised, and the page and control view state are restored.	During this event, the ASP.NET page framework restores the control properties and postback data.
User Code Initialization	The page's **Page_Load** event is raised.	Read and restore values stored previously: • Using the **Page.IsPostBack** property, check whether this is the first time the page is being processed. • If this is the first time the page is being processed, perform initial data binding. • Otherwise, restore control values. • Read and update control properties.
Validation	The Validate method of any validator Web server controls is invoked to perform the control's specified validation.	(There is no user hook at this stage. You can test the outcome of validation in an event handler.)
Event Handling	If the page was called in response to a form event, the corresponding event handler in the page is called during this stage.	Perform your application-specific processing: • Handle the specific event raised. **Note** Events are not raised in a particular order, except that cached control events — as specified by the control's **AutoPostBack** property — are always processed before the posting event. • If the page contains Types of Validation for ASP.NET Server Controls, check the **IsValid** property for the page and for individual validation controls. • Manually save the state of page variables that you are maintaining yourself. • Check the IsValid property of the page or of individual validation controls. • Manually save the state of controls dynamically added to the page.
Cleanup	The **Page_Unload** event is called because the page has finished rendering and is ready to be discarded.	Perform final cleanup work: • Closing files. • Closing database connections. • Discarding objects. **Note** It is important that expensive resources, such as database connections, be explicitly closed. Otherwise, they will remain open until the next garbage collection occurs. On a heavily loaded server, many open resources can adversely affect performance.

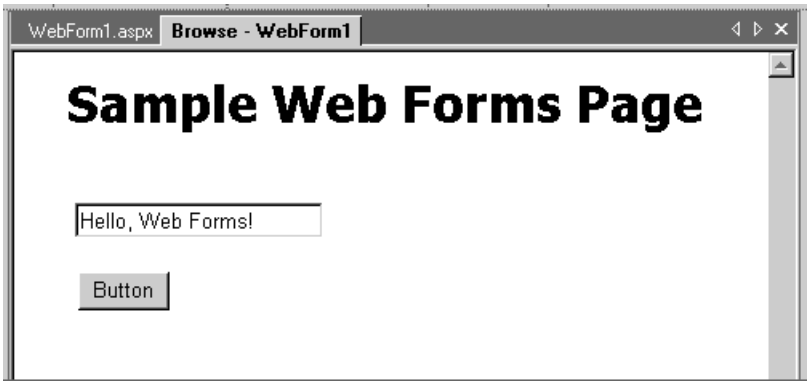
Walkthrough: Creating a Basic Web Forms Page

This walkthrough illustrates how to create a Web Forms page. You will see how to add controls to the page and create code for them that will run on the server. Tasks illustrated in this walkthrough include:

- Creating a new Web Forms page.
- Adding controls and static HTML text to the page.
- Creating an event handler for the control.
- Building and running the Web Forms page.

When you are finished, your Web Forms page will look something like the following:



Creating the Project and Form

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

   Tip If you already have a solution open, choose **Close Solution** so that your new Web Forms project will be part of its own solution.

   When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

Examining Web Forms Structure

Take a moment to see how Web Forms pages are structured and how the Web Forms Designer is laid out. The Web Forms Designer is open with a file called WebForm1.aspx. A Web Forms page consists of two separate files:

- The .aspx file contains the HTML text and the controls that make up the user interface of the page.
- A separate file, called WebForm1.aspx.vb or WebForm1.aspx.cs (depending on what language you specified for your project), contains the page's code — that is, it is the page's class file. It is sometimes referred to as the "code-behind" file. By default, Solution Explorer does not display the page's class file.

To see a page's class file in Solution Explorer

- Click the **Show All Files** button in the toolbar of Solution Explorer, then expand the node for WebForm1.aspx.

At the bottom of the Web Forms Designer are two tabs, **Design** and **HTML**, which show you different views of the .aspx file you are working with:

- Design view provides you with a WYSIWYG view where you can drag controls and use the Properties window to configure them.
- HTML view shows you the same information, but in the "raw" format of an HTML file. As in HTML files, the Web Forms Designer supports Intellisense for elements in HTML view.

You can work in either view. When you switch between them, each view is updated with changes you made in the other. As you will see later, you use the code editor to write code for the page's class file (.aspx.vb or .aspx.cs).

Adding Controls and Text

You can now add controls and text to the page.

Grid or Flow Mode

By default, the Web Forms page you are working with is in grid layout mode. In this mode, you can drag controls around the page and position them using absolute (x and y) coordinates. (For downlevel browsers, the controls are positioned using tables.)

If you prefer, you can work in flow layout mode, which is like a traditional HTML page — items are positioned from top to bottom. Each view has advantages: grid mode makes it easy to position items. In flow mode, it is easier to add static text. For details, see Positioning HTML Elements in Design View.

For this walkthrough, you will work in grid mode. You will learn how to position static text in this mode.

Adding Controls To Your Web Forms Page

Web Forms controls are called "server controls" because when the page runs, the controls are instantiated in server code as part of the page class. When users interact with the controls — for example, when users click a Web Forms button control — the code associated with the control runs on the server after the page is posted. In server code, you can write event handlers for server controls, set their properties, and so on.

Not every element on the Web Forms page is a server control. For example, by default, static HTML text is not a server control, and you cannot control it from server code. Even standard HTML controls (for example, an HTML submit button) are not server controls by default — they are not visible as first-class controls in server code. (HTML elements are programmable in client script, as in any HTML page.)

Therefore, to work with controls on a Web Forms page, you need to add them as server controls. Server controls come in two types:

- **HTML server controls** These are HTML elements that are marked (that you convert) to be programmable in server code. Typically, you convert HTML elements to HTML server controls only if you have some reason to want to program them from server code.
- **Web server controls** These are controls specific to Web Forms that provide more features than HTML server controls and do not map directly to HTML elements.

For more details about these controls, see Introduction to ASP.NET Server Controls.

In this section, you will add one of each type control.

To add an HTML server control to your Web Forms page

1. Click the Design tab at the bottom to switch to Design view.
2. From the **HTML** tab of the Toolbox, drag a **Text Field** element onto the page.

   Switch to HTML view to see that your action has added a tag similar to the following:

   ```
   <INPUT type="text">
   ```

3. Switch to Design view.
4. Convert the HTML text element to a server control by right-clicking it and choosing **Run As Server Control**.

   A glyph (▶) appears in the upper-left corner of the control to indicate that the control is a server control. Converting an HTML element makes it into an **HtmlInputText** server control.

   Two attributes are added to the HTML element as part of this conversion:

   - The **id** attribute identifies the control in your code. For the **HtmlInputText** server control, this attribute is set by

default to the name **Text1**.

- The **runat** attribute is set to **server**. This marks the element as a server control and makes it visible to the Web Forms server code as a programmable element.

To add a Web server control to your Web Forms page

- From the **Web Forms** tab of the Toolbox (not the **HTML** tab), drag a **Button** Web server control onto the page.

  Tip The **Web Forms** tab is only available when the designer is in Design view.

  This step creates a Web server control element in the designer rather than an HTML button. If you switch to HTML view, you will see the following:

  ```
  <asp:Button id="Button1" runat="server"></asp:Button>
  ```

  This element does not correspond directly to an HTML element. Instead, when the page runs, an instance of the Button Web server control is created and processed. During page processing, the control outputs some HTML elements into the page (in this case, an HTML `<input type=submit>` element).

Adding HTML Text to the Page

In grid layout mode, it is easy to position controls. But what about static HTML text? Because all the elements on the page are positioned with x and y coordinates, you cannot just type text into the page where you want it to appear, as you can in flow layout mode.

The solution is to add an HTML **Label** control in which you can add the static text. You can then position this label (essentially a <DIV> element) anywhere on the page.

To add static text in grid layout mode

1. From the **HTML** tab of the Toolbox, drag a **Label** control onto the page. Position it and size it for the text you want to enter.
2. Click the label to select it, and then click it again. (Do this slowly enough that you are not double-clicking the element.)

   The label is put into text-edit mode, which is marked by a shaded border.

3. Type the static text that you want. For example, type "Sample Web Forms Page".
4. Select the text and then use the tools on the Formatting toolbar to set the text's block format, font, size, and so on.
5. Click away from the label to leave text-edit mode.

Creating an Event Handler

Server controls on Web Forms pages can raise various events. Many events are triggered by something the user does in the browser. For example, a **Button** Web server control can raise a **Click** event when a user clicks a button on your page.

The code to handle the raised event is executed on the server. When the user clicks a button, the page is posted back to the server. The ASP.NET page framework parses the event information, and if you have an event handler corresponding to the event, your code is called automatically. When your code finishes, the page is sent back to the browser with any changes as a result of the event handler code.

To create an event handler for the Button Web server control

1. Double-click the **Button** Web server control.

   The designer opens the class file for the current form and creates a skeleton event handler for the button control's **Click** event. The code will look like this:

   ```
   ' Visual Basic
   Private Sub Button1_Click(ByVal sender as System.Object, ByVal e as System.EventArgs) Han
   dles Button1.Click

   End Sub

   // C#
   private void Button1_Click(object sender, System.EventArgs e)
   ```

```
{

}
```

2. Write code in the method to display a message in the **HtmlInputText** server control by setting its **Value** property. For example:

```
' Visual Basic
Private Sub Button1_Click(ByVal sender as System.Object, ByVal e as System.EventArgs) Han
dles Button1.Click
   Text1.Value = "Hello, Web Forms!"
End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e)
{
      Text1.Value = "Hello, Web Forms!";
}
```

Building and Running the Web Forms Page

Before you run your Web Forms page, you must compile the page's class file. You can then view the page in any browser.

To build and run the page

1. In Solution Explorer, right-click the WebForm1.aspx page, and then select **View in Browser**.

   Visual Studio compiles the page and displays it in the **Browse tab**.

2. Click the button on your Web Forms page.

   The text "Hello, Web Forms!" appears in the text box.

3. To stop running the form and return to design mode, close the **Browse** tab.

Next Steps

This is a simple Web Forms page, but it illustrates the fundamental steps that you use to create and edit Web Forms. From this start, you can begin to explore the tools provided in Visual Studio to help you create sophisticated Web applications. Suggestions for more exploration include:

- Investigate the types of controls you can use on Web Forms pages. For details, see Introduction to ASP.NET Server Controls.
- Experiment with working in flow layout mode instead of grid layout mode. For details, see Positioning HTML Elements in Design View.
- Check user input into your Web Forms page using validation controls. For details, see Introduction to Validating User Input in Web Forms.
- Explore the use of more complex controls such as the **Calendar** Web server control. For details, see Calendar Web Server Control.
- Learn about the security issues associated with Web Forms. For details, see Overview of Web Application Security Threats.
- Bind the form to a data source and display data in individual controls or in complex controls on the form. For more information, see Data Access in Web Forms Pages. Controls such as the **DataList** and the **DataGrid** are provided to ease the implementation of including data-driven user interfaces. For more information, see Introduction to the DataList Web Server Control and Introduction to the DataGrid Web Server Control.

Migrating to Web Forms

If you have used earlier versions of Microsoft Visual Studio or individual products such as Visual Basic or Visual InterDev, you may have existing Web applications based on previous Web programming technology. Migrating these Web applications to the Web Forms code model allows you to take advantage of all the extended features of ASP.NET.

In This Section

Migrating ASP Pages to Web Forms Pages
Provides instruction on how to migrate an Active Server Pages (ASP) page to an ASP.NET Web Forms page.
Migrating HTML Pages to Web Forms Pages
Provides instruction on how to migrate an HTML page to an ASP.NET Web Forms page.

Upgrading WebClass Projects to Visual Basic .NET
Explains how to upgrade WebClass projects (also known as IIS Applications) to ASP.NET Web Application projects.

Migrating ASP Pages to Web Forms Pages

You can work with and run existing ASP pages (.asp files) as-is in Visual Studio. You can use ASP pages and ASP.NET pages in the same project. You can edit ASP files in the Web Forms Designer and run them as you would other pages in your project.

> **Note** Some ASP and Visual InterDev 6.0 features are not supported by ASP.NET, because these features require a different run-time environment. For more information, see Migrating ASP Pages to ASP.NET.

However, you might find it useful to convert ASP pages to ASP.NET Web Forms pages so that you can take advantage of the enhanced features of the newer architecture, including the benefits of using ASP.NET server controls and better performance and scaling.

Migrating an ASP page to a Web Forms page accomplishes the following:

- Creates the proper file extension for the page.
- At your option, generates a code-behind class file for the page.
- Corrects certain HTML syntax that was allowed in ASP files but is not allowed in Web Forms pages. For example, the Web Forms Designer will put quotation marks around any ASP code used to set attribute values in an element.
- Adds the appropriate page directives to the page so that it is linked with the code-behind file. For details, see @ Page.

The migration does not do the following:

- Convert inline ASP code (delimited with <% and %>) to code in the class file. However, the existing ASP code will work properly when the page runs.
- Convert VBScript code to Visual Basic .NET. You will need to fix errors that arise out of syntax problems, as documented below.
- Convert Visual InterDev design-time controls (DTCs) to Web Forms controls. If you have a DTC on the page, Visual Studio substitutes a placeholder. The DTC will not operate at run time. It is recommended that you replace DTCs with ASP.NET server controls.
- Convert existing HTML elements to HTML server controls or Web server controls. You can perform this step manually after the migration, as noted below.
- Configure the page to be able to run COM+ 1.0 components. You can enable COM interoperability by setting the ASPCompat attribute of the page's @ Page directive. For resources that discuss COM interoperability, see "Additional Information" below.
- Convert ADO data access code to ADO.NET. Using ADO in a Web Forms page requires COM interoperability. (See previous point.) For resources, see "Additional Information" below.

When the migration is complete, you can run the page normally. Generally, however, after performing the migration you will want to do further work on the page, such as substituting ASP.NET server controls for existing HTML elements.

To migrate an ASP page into a Web Forms project

1. In Solution Explorer right-click the project, point to **Add**, then click **Add Existing Item**.
2. In the **Add Existing Item** dialog box, find the ASP page to migrate, then choose **Open**.

   > **Tip** In the **Files of type** box, select **Web Files** to view all Web files.

   When you migrate the file, it is physically copied from the file's original location to the location of your Web Forms project, and it appears in Solution Explorer.

3. In Solution Explorer, right-click the file name, choose **Rename**, and change the file name extension to ".aspx".

   This causes two confirmation dialog boxes to appear, one after the other.

4. Do the following:
   a. The first dialog box notes that changing the file name extension may invalidate the file format for use with some applications. Click **Yes.**
   b. The second dialog box indicates that there is no code-behind class file associated with the new .aspx file. Click **Yes** to add the code-behind class file.

      > **Tip** You can click the **Show All Files** button in Solution Explorer to see all the files associated with this project. If you expand the tree below your newly migrated file, you should see the code-behind class file.

5. Open the new .aspx file.

   By default, the file opens in Design view. If there are syntax errors on the page, the designer will open the file in HTML view. In that case:

   a. Try switching to Design view. It will not be displayed; instead you will see a message indicating syntax errors.
   b. Fix the errors and try switching to Design view again.

   > **Note** By default, switching between views causes the Web Forms Designer to apply automatic formatting. This can fix some syntax errors, such as missing quotation marks. For details, see Format, HTML/XML, Text Editor, Options Dialog Box.

6. In HTML view, inspect the file to ensure that the file contains an HTML `<form>` element within the HTML `<body>` tags. If not, add a `<form>` element. In the opening tag, add the `Runat = "server"` attribute so that it looks similar to the following:

```
<form id="Form1" method="post" runat="server">
```

7. Determine whether the file contains calls to COM components — for example, ADO code. If so, add the **AspCompat** attribute to the page directive in HTML view:

```
<%@ Page [...] AutoEventWireup="false" AspCompat="true" %>
```

8. Save the form, compile the project, and view the page in the browser. For details see Compiling and Running Web Forms Pages.
9. Check for issues that appear in the Task List window and resolve them. For more information see Task List Window.
10. Repeat Steps 8 and 9 until your form is working properly.

At this point, you will not have any server controls on the page. However, you can convert existing HTML controls to HTML server controls. For details, see Converting HTML Server Controls to HTML Elements.

You only need to migrate the controls that you want to be accessible to server code during run time. The HTML controls that you do not migrate will behave as before.

> **Note** If you wish to add additional ASP.NET server controls to your newly migrated Web Forms page, you must close the file and open it again for the Web Forms Designer to properly initialize the Web Forms tab of the Toolbox. You may then drag server controls to your Web Forms page.

Additional Information

This topic offers only an overview of how to convert ASP pages to Web Forms pages. For more information, including language issues, COM compatibility, and more, see the following sources:

- The technical article Migrating to ASP.NET: Key Considerations
- The technical article Converting ASP to ASP.NET.

Migrating HTML Pages to Web Forms Pages

You can work with and run existing HTML pages as-is in Visual Studio. You can edit the files in the HTML Designer and run them as you would other pages in your project. However, if the HTML page includes a form or if it relies on browser-sensitive client script, you might find it useful to convert the page to an ASP.NET Web Forms page.

Migrating an ASP page to a Web Forms page accomplishes the following:

- Creates the proper Web Forms file extension for the page.
- At your option, generates a code-behind class file for the page.
- Adds the appropriate page directives to the page so that it is linked with the code-behind file. For details, see @ Page.

The migration does not do the following:

- Convert existing HTML elements to HTML server controls or Web server controls. You can perform this step manually after the migration.
- Convert client script (in JavaScript or VBScript) to Web Forms ASP.NET code. Client script will run without modification in Web Forms pages, since it runs entirely in the browser. However, you might want to reimplement the same functionality in Web Forms server code instead so that there are no browser dependencies in the page.

When the migration is complete, you can run the page normally. Generally, however, after performing the migration you will want to do further work on the page, such as converting existing HTML elements to ASP.NET server controls.

To migrate an HTML page into a Web Forms project

1. In Solution Explorer, right-click the project, point to **Add**, then click **Add Existing Item**.
2. In the **Add Existing Item** dialog box, find the HTML page to migrate, then choose **Open**.

   > **Tip** In the **Files of type** box, select **Common Web Files**.

   When you migrate the file, it is physically copied from the file's original location to the location of your Web Forms project, and it appears in Solution Explorer.

3. In Solution Explorer, right-click the file name, choose **Rename**, and change the file name extension to ".aspx".

   This causes two confirmation dialog boxes to appear, one after the other.

4. Do the following:
   a. The first dialog box notes that changing the file name extension may invalidate the file format for use with some applications. Click **Yes.**
   b. The second dialog box indicates that there is no code-behind class file associated with the new .aspx file. Click **Yes** to add the code-behind class file.

   > **Tip** You can click the **Show All Files** button in Solution Explorer to see all the files associated with this project. If you expand the tree below your newly migrated file, you should see the code-behind class file.

5. Open the new .aspx file.

   By default, the file will open in Design view. If there are syntax errors on the page, the designer will open the file in HTML view. In that case:

   a. Try switching to Design view. It will not be displayed; instead you will see a message indicating syntax errors.
   b. Fix the errors and try switching to Design view again.

   > **Note** By default, switching between views causes the Web Forms Designer to apply automatic formatting. This can fix some syntax errors, such as missing quotation marks. For details, see Format, HTML/XML, Text Editor, Options Dialog Box.

6. In HTML view, inspect the file to ensure that the file contains an HTML `<form>` element within the HTML `<body>` tags. If not, add a `<form>` tag one and in the opening form tag, set the attribute `Runat = "server"` attribute so that it looks similar to the following:

```
<form id="Form1" method="post" runat="server">
```

7. Save the form, compile the project, and view it in the browser. For details see Compiling and Running Web Forms Pages.
8. Check for issues that appear in the Task List window and resolve them. For more information see Task List Window.
9. Repeat Steps 7 and 8 until your form is working properly.

At this point, you will not have any server controls on the page. However, you can convert existing HTML control to HTML server controls. For details, see Converting HTML Server Controls to HTML Elements.

You only need to migrate the controls that you want to be accessible to server code during run time. The HTML controls that you do not migrate will behave as before. For more information, see Adding HTML Server Controls to a Web Forms Page.

> **Note** If you wish to add additional Web server controls to your newly migrated Web Forms page, you must close the file, and open it again for the Web Forms Designer to properly initialize the **Web Forms** tab of the Toolbox. You may then drag Web server controls to your Web Forms page. For more information, see Introduction to ASP.NET Server Controls.

Walkthrough: Creating an Accessible Web Application

Creating accessible Web pages allows you to reach as many customers as possible. People with disabilities are not the only users that appreciate accessible pages. Users with slow connections or text-only browsers also rely on accessibility options. Accessible design allows automation tools such as search engines to search, index, and manipulate the information on your pages. Finally, future telecommunications laws may require information distributed over the Internet to be accessible in the same manner as traditional software.

For more information, see Accessibility Design Guidelines for the Web.

From Microsoft's Accessibility Web site, here are the "12 Tips for Designing Accessible Web Pages":

- Good alternative(ALT) text for all graphics.
- Proper use of image maps.
- Useful link text.
- Good keyboard navigation.
- Alternates to all controls and applets.
- Alternate pages that do not use frames.
- Proper use of tables and their alternatives.
- Support the reader's formatting options.
- Do not require the use of style sheets.
- File formats the reader can use.
- Avoid using scrolling marquees.
- Provide titles for most objects.

If you are unable to meet accessibility goals, consider providing alternate text-only Web pages.

Planning Ahead for Accessibility

Controls on the standard toolbox for Web Forms support many of the accessibility guidelines, including exposing the keyboard focus and exposing the screen elements. The controls' properties can be used to support other accessibility guidelines as shown in the following table.

Control Property	**Accessibility Considerations**
TabIndex	Use the **TabIndex** property to create a sensible navigational path through the form. It is important for controls without intrinsic labels, such as text boxes, to have their associated label immediately precede them in the tab order.
Text	Use the HTML <u> tag to display the access key for a control. Using access keys contributes to providing documented keyboard access to all features. (Use the **AccessKey** property to enable an access key for a control.)
Font Size	Use heading tags rather than specific sizes.
Alternate Text	Supply alternate text for all images.
AccessKey	Use this property to provide keyboard access to controls.

Creating the Project

This walkthrough creates a Web site for an algebra class. The user interface consists of an **Image** for the class logo, a **Panel** with a few **HyperLinks** for lectures, a **DataGrid** to display a table containing the class syllabus, and a **HyperLink** to a page describing the class textbook.

The focus of this walkthrough is the accessibility of the user interface, and how to code against the Web Server controls to support accessibility. It demonstrates the accessibility features of several frequently used controls, including the **Link**, **DataGrid**, **Image**, and **Label** controls. The **HyperLink**s will all navigate to the same Web page, but that Web page will be blank.

To begin making the application

1. Create a new ASP.NET Web Application in either Visual Basic or Visual C#. Name the project **AlgebraClass**. (For details see Creating New Solutions and Projects.)

   The start-up form, WebForm1.aspx, appears in the Web Forms Designer.

2. On the **Project** menu, click **Add Web Form**. The **Add New Item** dialog box appears. Name the new Web Form Lecture.aspx and click **Open**. This form will be used to provide the **NavigationUrl** for the **HyperLink** examples on WebForm1.
3. Close the form named Lecture.aspx, saving the changes.

Adding the Controls to the Form

When adding the controls to the form for this application, keep in mind the following guidelines in order to make an accessible application:

- When using tables, use the TITLE attribute to provide names for the columns and rows of a table. Also, make sure that tables make sense if read left-to-right, top-to-bottom.
- Use real heading tags, for example, H1, H2, and so on, rather than formatted text, to support the user's selected formatting options.
- Provide useful link text. For example, if the text is "Click here for Lecture 1 notes", "Lecture 1 notes" is more useful link text than "Click here".
- Provide a sensible navigational path through the page, following the normal flow of text for the given language.
- Use the TITLE attribute for most objects.

To add accessible controls to your page

1. In the Properties window, select **Document**, and set the following properties:

   - Set the **title** property to "Algebra Class"
   - Set the **bgColor** to the **Background** color of the **System Colors** set.

     To do this, click the ellipses button (...) to open the **Color Picker** dialog box, choose the **System Colors** tab, and click **Background**.

   - Seth the **pageLayout** property to **GridLayout**.

2. Add the controls to the form from the Web Forms tab of the Toolbox. In the Properties window, set the properties as described below. See the picture at the end of the table for a model of how to arrange the controls on the form. For more information about adding controls to Web Forms pages, see Adding Web Server Controls to a Web Forms Page.

   To correctly position the **HyperLink** controls on the **Panel** control, you will need to select the **Panel** control and then position your pointer in the **Panel**. The **HyperLink** will be added at the pointer position. You will need to add a carriage return at the end of the first hyperlink to vertically align the second hyperlink.

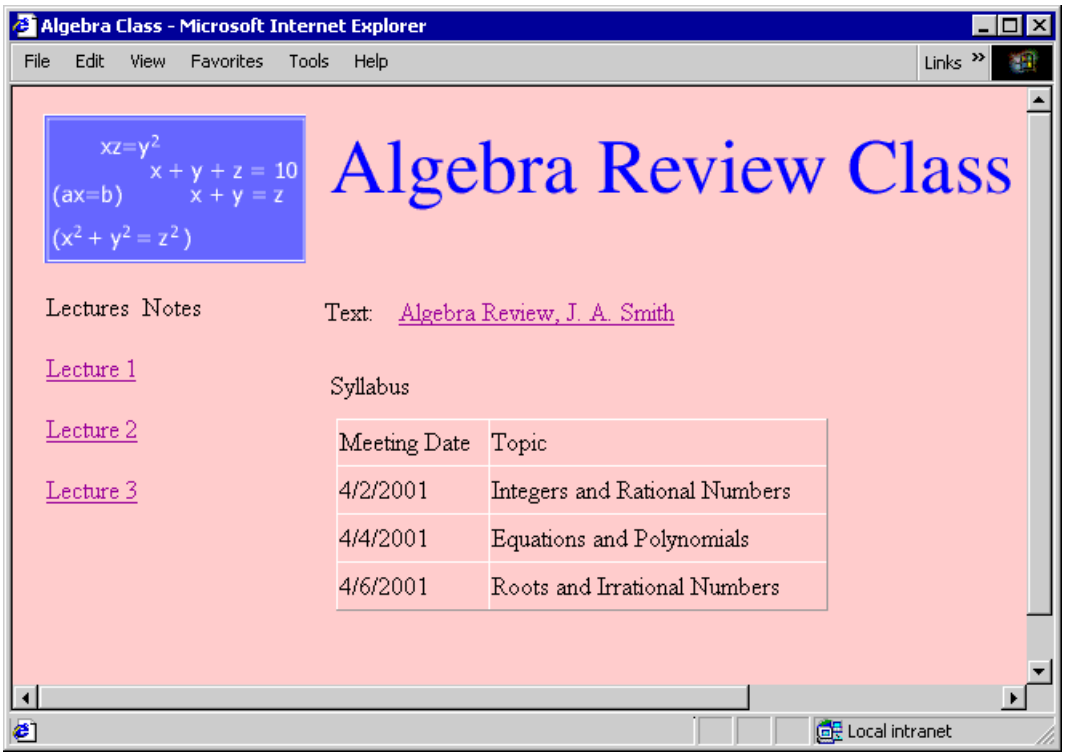
Object	Property	Value
Image	AlternateText	Algebra equations.
	ImageUrl	Any bitmap
	TabIndex	0
Label	ID	ClassName
	ForeColor	"Control" on the **System** Tab of the color palette. Click (...) to access the color palette.
	Text	Algebra Review Class
	Font Size	XX-Large
	TabIndex	1
Panel	ID	Lectures
	TabIndex	2
HyperLink (add to Lectures panel)	ID	Lecture1
	Text	Lecture 1
	AccessKey	1
	NavigateUrl	Lecture.aspx
	TabIndex	3
HyperLink (add to Lectures panel)	ID	Lecture2
	Text	Lecture 2

	AccessKey	2
	NavigateUrl	Lecture.aspx
	TabIndex	4
HyperLink (add to Lectures panel)	ID	Lecture3
	Text	Lecture 3
	AccessKey	3
	NavigateUrl	Lecture.aspx
	TabIndex	5
Label	ID	TextbookLabel
	Text	Text:
	TabIndex	6
Hyperlink	ID	TextbookLink
	Text	Algebra Review, J. A. Smith
	NavigateUrl	Lecture.aspx
	TabIndex	7
Label	ID	SyllabusTitle
	Text	Syllabus
	TabIndex	8
DataGrid	ID	SyllabusGrid
	TabIndex	9

3. In the designer, select the **Panel** control. In the designer, change the text of the panel to **Lecture Notes**.
4. In the designer, click the HTML tab. Modify the HTML tag to indicate that the language of the page is English.

```
<HTML lang="en">
```

Your form will look something like the following at run time:



To add functionality to the form and its controls

1. Add the following function to create data for the **DataGrid**. In most applications, you would retrieve your data from a database, but for this application, the following method is sufficient.

```
' Visual Basic
Function CreateSyllabusEntries() As DataTable
   Dim syllabus As New DataTable()
```

```
   syllabus.Columns.Add("Meeting Date", GetType(String))
   syllabus.Columns.Add("Topic", GetType(String))
   syllabus.Rows.Add(New Object() {"4/2/2001", _
      "Integers and Rational Numbers"})
   syllabus.Rows.Add(New Object() {"4/4/2001", _
      "Equations and Polynomials"})
   syllabus.Rows.Add(New Object() {"4/6/2001", _
      "Roots and Irrational Numbers"})
   Return syllabus
End Function

// C#
protected DataTable CreateSyllabusEntries()
{
   DataTable syllabus = new DataTable();
   syllabus.Columns.Add("Meeting Date",
      System.Type.GetType("System.String"));
   syllabus.Columns.Add("Topic", System.Type.GetType("System.String"));
   syllabus.Rows.Add(new object[] { "4/2/2001",
      "Integers and Rational Numbers" } );
   syllabus.Rows.Add(new object[] { "4/6/2001",
      "Equations and Polynomials" } );
   syllabus.Rows.Add(new object[] { "4/8/2001",
      "Roots and Irrational Numbers" } );
   return syllabus;
}
```

2. Edit the `Page_Load` method to bind the syllabus data to the **DataGrid**.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   Dim syllabus As DataTable = CreateSyllabusEntries()
   SyllabusGrid.DataSource = syllabus
   SyllabusGrid.DataBind()
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   DataTable syllabus = CreateSyllabusEntries();
   SyllabusGrid.DataSource = syllabus;
   SyllabusGrid.DataBind();
}
```

3. Use the **ItemCreated** event of the DataGrid to add TITLE attributes to the table cells created by the DataGrid. At a minimum, you should set the TITLE for the column headers. You may also want to set the TITLE for rows. For information on event handlers, see Creating Event Handlers in Web Forms Pages.

```
' Visual Basic
Private Sub SyllabusGrid_ItemCreated(ByVal sender As Object, _
ByVal e As System.Web.UI.WebControls.DataGridItemEventArgs) _
Handles SyllabusGrid.ItemCreated
   Dim cells As TableCellCollection = e.Item.Cells
   If e.Item.ItemType = ListItemType.Header Then
      ' Add TITLE attributes to the column headers.
      cells.Item(0).Attributes.Item("TITLE") = "Date"
      cells.Item(1).Attributes.Item("TITLE") = "Topic"
   ElseIf (e.Item.ItemType = ListItemType.Item) _
```

```
      Or (e.Item.ItemType = ListItemType.AlternatingItem) Then
      ' Add descriptive titles to individual cells.
      Dim rowView As DataRowView = _
         CType(e.Item.DataItem, DataRowView)
      cells.Item(0).Attributes.Item("TITLE") = _
         rowView.Row.ItemArray(0).ToString()
      cells.Item(1).Attributes.Item("TITLE") = _
         rowView.Row.ItemArray(1).ToString()
   End If
End Sub

// C#
private void SyllabusGrid_ItemCreated(object sender, System.Web.UI.WebControls.DataGridIt
emEventArgs e)
{
   TableCellCollection cells = e.Item.Cells;
   if (e.Item.ItemType == ListItemType.Header)
   {
      // Add TITLE attributes to the column headers.
      cells[0].Attributes["TITLE"] = "Date";
      cells[1].Attributes["TITLE"] = "Topic";
   }
   else if ((e.Item.ItemType == ListItemType.Item) ||
      (e.Item.ItemType == ListItemType.AlternatingItem))
   {
      // Add descriptive titles to individual cells.
      DataRowView rowView = (DataRowView)e.Item.DataItem;
      cells[0].Attributes["TITLE"] =
         rowView.Row.ItemArray[0].ToString();
      cells[1].Attributes["TITLE"] =
         rowView.Row.ItemArray[1].ToString();
   }
}
```

4. Run the application.

Testing the Application

Use the following checklist to test the accessibility of the application.

- Test the access keys. For this application, you defined the access keys ALT+1, ALT+2, and ALT+3 for the **HyperLink** controls. The access keys will take you to the links. Press ENTER to follow the links.
- Turn off graphics to make sure that the ALT text displayed makes the page usable. In Internet Explorer version 6, click the Tools menu and choose the Internet Options command. In the Advanced tab, turn off the graphics options in the Multimedia section. You must refresh the page to see the ALT text.
- Turn off sounds to make sure that no important instructions are lost. In Internet Explorer, version 6, click the Tools menu and choose the Internet Options command. In the Advanced tab, turn off the graphics options in the Multimedia section.
- View the application in a browser that allows you to turn off style sheets. Turn off the style sheets to make sure the page is still readable.
- Use the High Contrast option and make sure the page is still readable. To test support of High Contrast, choose the **Accessibility Options** icon in **Control Panel**. Click the **Display** tab and select the **Use High Contrast** check box. Navigate through all user interface elements to ensure that the color and font changes are reflected. Also, ensure that images or patterns drawn behind text are omitted.

  > **Note** Windows NT 4 does not have an **Accessibility Options** icon in **Control Panel**. Thus, this procedure for changing the **SystemInformation.HighContrast** setting does not work in Windows NT 4.

- Use custom font sizes in the Display section of the Control Panel.
- Use the largest font size supported (available only when High Contrast is selected) to make sure the page is still readable.

- Resize the browser window and check the readability.
- Navigate using the keyboard to make sure the navigational order is sensible, that the TAB key traverses all links, and that CTRL+TAB moves between panes or sections.
- Select all text and copy it to the clipboard to make sure that it makes sense.
- See the Bobby Web site for an analysis tool you can use to examine your pages (http://www.cast.org/bobby/).

Working with Web Projects
Provides details on project management when making your ASP.NET Web application.

Web Forms Pages and Projects in Visual Studio

Web Forms pages are one way to create the user interface of an ASP.NET-based Web application. You can add Web Forms pages to several types of Visual Studio projects. Most often, when you want to work with Web Forms pages, you will use the ASP.NET Web Application project template. For more information on Web project templates, see Introduction to Web Projects. For information on ASP.NET Web applications as a whole, see Introduction to ASP.NET Web Applications in Visual Studio.

To work with a Web Forms page in Visual Studio, you use the Web Forms Designer. The designer includes a WYSIWYG view, called Design view, for laying out the elements of the page. Alternatively, you can switch the designer to HTML view, which gives you direct access to the ASP.NET syntax of the elements on the page. Finally, the designer includes a code editor with Intellisense that you can use to create the page initialization and event handler code for your page. For more information, see Introduction to Web Forms Pages.

Project Files Created With Web Forms

When you create a Web project, Visual Studio constructs a Web application directory structure on the target Web server, and a project structure on your local computer. The files that relate to your Web Forms pages are as follows:

> **Note** You need to have appropriate privileges on the Web server computer to create and manage Web application files. The correct way to get those privileges is to be a member of the VS Developers group that is automatically created on the Web server. For details, see Web Application Security at Design Time in Visual Studio.

File Created	Description
WebForm1.aspx and WebForm1.aspx.vb files (or WebForm1.aspx.cs for Visual C# Web applications)	These two files make up a single Web Forms page. The .aspx file contains the visual elements of the Web Forms page, for example HTML elements and Web Forms controls. The WebForm1.aspx.vb class file is a hidden, dependent file of WebForm1.aspx. It contains the code-behind class for the Web Forms page, containing event-handler code and the like. For more information see Web Forms Code Model.
AssemblyInfo.vb (for Visual Basic projects) or AssemblyInfo.cs (for C# projects)	A project information file (AssemblyInfo.vb or AssemblyInfo.cs file) that contains metadata about the assemblies in a project, such as name, version, and culture information. For details on data contained in the assembly file, see Assembly Manifest.
Web.config	An XML-based file that contains configuration data on each unique URL resource used in the project. For more information see Application Configuration Files.
Global.asax and Global.vb or Global.cs files	An optional file for handling application-level events. This file resides in the root directory of an ASP.NET application. The Global.vb class file is a hidden, dependent file of Global.asax. It contains the code for handling application events such as the **Application_OnError** event. At run time, this file is parsed and compiled. For more information on Global.asax file usage, see Global.asax File.
Styles.css	A cascading style sheet file to be used within the project. For more information see Introduction to Cascading Style Sheets.

Deployment

The server on which you create your Web Forms pages is typically not the server on which you will deploy the pages and their associated files for production. To deploy a Web project containing Web Forms pages, you may follow one of two approaches:

- Copy your project to the Web server
- Create a deployment project

For more information on these options, see Deployment of a Web Setup Project.

See Also

Working with Web Projects | Using Solution Explorer | Web Access Methods | Introduction to Solutions, Projects, and Items |

Adding Web Forms Pages to a Web Project

After you have started a Web project, you can create new Web Forms pages and add existing Web Forms pages to the project. For instructions on creating an ASP.NET Web application, see Creating Web Projects.

> **Note** You can add a Web Forms page to an existing Web project or add a page from another project. However, all pages in a single project must use the same programming language. For example, you cannot add a Visual C# Web Forms page to a Visual Basic project or vice versa.

Visual Studio enables shared working arrangements. A development team could split the development of new Web Forms pages between members, write code individually in separate projects and, using source control, add them to a single project. For more information on source control, see Source Control Basics.

When you create a Web Forms page, Visual Studio performs the necessary operations to include this file in your project. For an overview, see Web Forms Pages and Projects in Visual Studio.

To create a Web Forms page

1. In Solution Explorer, right-click the project name, click **Add**, then click **Add Web Form**.

   The **Add New Item** dialog box is displayed.

2. In the **Categories** pane, verify the **Web Project Items** node is highlighted and select **Web Form** in the **Templates** pane.
3. Supply a name for the form in the **Name** box at the bottom, then click **Open**.

   The new Web Forms page is created and displayed in the Web Forms Designer. If you want to give your form a different name, rename it in Solution Explorer. For an overview of managing Web Form pages, see Creating and Managing Web Forms Pages.

To add an existing Web Forms page to a project

1. In Solution Explorer, right-click the project name and click **Add**, then click **Add Existing Item**.

   The **Add Existing Item** dialog box is displayed.

2. Navigate to the directory containing the Web Forms page, select the page, and click **Open**.
3. If the existing file does not have a code-behind class file (.aspx.vb or .aspx.cs file), Visual Studio prompts you to create one. Typically, if the file page you are adding is a single-file Web Forms page, you do not need to create a code-behind class file, and you can click **No**.

   The Web Forms page is added to the project and opened in Design view.

   > **Note** When you add an existing file, the file is copied to your project. (The file is not simply added by reference). If you change the file in your project, the original file is left unchanged.

You can also rename a page by renaming it in Solution Explorer.

To change the name of a Web Forms page in a project using Solution Explorer

1. In Solution Explorer, right-click the file you want to change and click **Rename**.
2. Type the new file name you want, then press ENTER.

Compilation and Deployment of Web Projects

When using Visual Studio .NET to create ASP.NET Web applications, you use a standard deployment model: your project is compiled and the resulting files are deployed. The Web Forms code-behind class file (.aspx.vb, or .aspx.cs), but not the .aspx file, is compiled into a project .dll file along with all other class files included in your project. This single project .dll file is then deployed to the server, without any source code. When a request for the page is received, the project .dll file is instantiated and executed.

> **Note** For more information about how Web Forms pages are compiled, see Web Forms Code Model.

An implication of this model is that you can change the .aspx file after the project is built, but you cannot change the code in the class file without recompiling. In other words, you can change visual elements of your Web Forms pages without the need for recompiling and redeploying.

> **Security Note** At design time in Visual Studio, your code in your project always runs fully trusted. This has two implications. The first is that you can potentially run unsafe code by importing it into your project and running it as fully trusted. The second is that code in your project might work properly when you are testing it on your own computer, but might fail due to lack of adequate permissions in a deployed application. For more information, see Code Access Security.

Compiling and Deploying an ASP.NET Web Application Project

Suppose you have a simple ASP.NET Web application project called WebApplication1 that contains the following:

- A Web Forms page called WebForm1.aspx.
- Some additional modules containing business logic, written in the language of your choice, called BusinessLogic1 (.vb or .cs) and BusinessLogic2 (.vb or .cs).

You have edited the Web Forms page and are ready to compile the project. The following occurs when you compile it:

- All files in the project that have been modified since the last build are saved.
- The WebForm1.aspx file and default project files are copied to the Web server.
- The WebForm1 class file (.aspx.vb or .aspx.cs), BusinessLogic1 component, and BusinessLogic2 component are compiled into the project .dll file, which is copied to the server in the default \Bin directory of the target virtual directory.

> **Note** If there are compilation errors, the deployment will not succeed. For more information on compiling an ASP.NET Web application project, see Compiling and Running Web Forms Pages. For more information on deployment, see Deploying Applications and Components.

Compiling and Running Web Forms Pages

Compiling and Running Web Forms Pages

When you are ready to build and run your Web Forms page, you must first compile the ASP.NET Web application project. Once the Web application is compiled, the pages included within it can be run. There are three methods you can utilize to build the application and run your Web Forms page.

Method	Description
With the debugger	Starts the default browser and loads the specified start page. Running a page in the debugger allows you to step through code line by line and make use of additional analysis tools and run-time information. If Visual Studio detects that key files have changed, it will also build the project before launching the browser with the specified start page. **Note** In order to run a project with the debugger, you must be a member of the Debugger Users group on the server computer, and the computer must be configured to support debugging. For details, see Introduction to Web Application Debugging.
Without the debugger	Allows you to run your code as it normally would run outside of the context of development tools, and therefore no run-time information is available through these tools. If Visual Studio detects that key files have changed, it will build the project before launching the browser with the specified start page.
View in Browser	Compiles the project and opens a Web page chosen from Solution Explorer. The project is compiled and run in the default browser within Visual Studio.

Note When your Web application runs, it executes within the context of a special local user, called ASPNET, that determines the permissions that your application will have to access resources. For details, see Access Permissions for Web Applications.

To build and run a Web Forms page with the debugger

1. In Solution Explorer, right-click your Web Forms page and click **Set As Start Page**.
2. On the **Debug** menu, click **Start**. This command instructs Visual Studio to run the ASP.NET Web application in the debugger.
3. To stop running the form and return to design mode, close the browser, or on the **Debug** menu click **Stop Debugging**.

Tip F5 is the keyboard shortcut for **Start**, and SHIFT+F5 is the keyboard shortcut for **Stop Debugging**.

To build and run a Web Forms page without the debugger

1. In Solution Explorer, right-click your Web Forms page and click **Set As Start Page**.
2. On the **Debug** menu, click **Start without Debugging**. Visual Studio saves all files in the project and then builds it. The project's start page is launched in the default browser.

   Tip CTRL+F5 is the keyboard shortcut for **Start without Debugging**.

3. To stop running the form and return to design mode, close the browser, or click **Stop Debugging** on the **Debug** menu.

To build and run a Web Forms page using the View in Browser feature

1. In Solution Explorer, right-click the Web Forms page you want to preview, and click **View in Browser**.
2. Visual Studio builds the ASP.NET Web application and launches the specified start page within the default browser. The page is labeled **Preview** in the Visual Studio environment.
3. To stop running the preview, close the preview page.

Web Forms Page Processing
Explains how Web Forms pages are processed, including what stages (events) they go through and what you can do at each stage.
ASP.NET Server Controls
Describes the controls available for use on Web Forms pages.

Server Event Handling in Web Forms Pages

As with traditional forms, when you work with server controls on a Web Forms page, much of the page's logic involves responding to events raised by controls. However, events work somewhat differently in Web Forms pages than in client-based forms such as Windows Forms.

The following topics explain the event-handling model for Web Forms pages and provide instructions on how to create event handlers.

In This Section

ASP.NET Server Control Event Model
Explains how events that originate on the client (browser) are handled in server-side code.
Creating Event Handlers in Web Forms Pages
Gives details on how to create event handlers using the Web Forms Designer.
Binding to an Existing Event Handler in Web Forms Pages
Gives details on how to bind an existing event handler to an event in Web Forms pages.
Creating an Event Handler at Run Time in Web Forms Pages
Gives details on how to create event handlers for an event at run time.
Connecting Multiple Events to a Single Event Handler in Web Forms Pages
Gives details on how to connect multiple events to a single event handler in Web Forms pages at run time.

ASP.NET Server Controls
Describes the controls available for use on Web Forms pages.

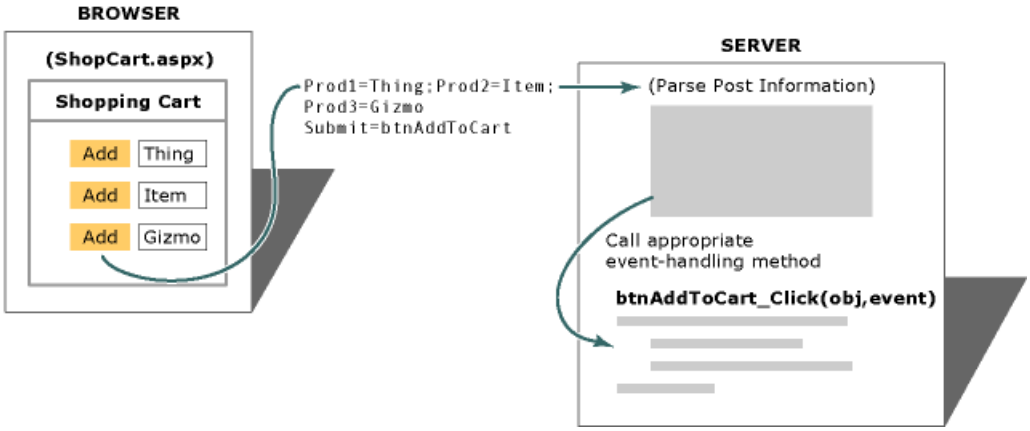
ASP.NET Server Control Event Model

Events raised by ASP.NET server controls work somewhat differently than events in traditional client forms or in client-based Web applications. The difference arises primarily because of the separation of the event itself from where the event is handled.

In client-based applications, events are raised and handled on the client. In Web Forms pages, on the other hand, events associated with server controls are raised on the client but handled on the Web server by the ASP.NET page framework.

For events raised on the client, the Web Forms control event model requires that the event information be captured on the client and an event message transmitted to the server, via an HTTP post. The page framework must interpret the post to determine what event occurred and then call the appropriate method in your code on the server to handle the event. For more information, see Events in ASP.NET Server Controls.

The Web Forms control event model



ASP.NET handles virtually all the mechanics of capturing, transmitting, and interpreting the event. When you create event handlers in a Web Forms page, you can do so without thinking about the mechanics of how the event information is captured and made available to your code. Instead, you can create event handlers in much the same way you would do so in a traditional client form. Even so, there are some aspects of event handling in Web Forms pages that you should be aware of.

Intrinsic Event Set

Because most Web Forms events require a round trip to the server for processing, they can affect the performance of a form. Therefore, server controls offer a limited set of intrinsic events, usually only click-type events. Some server controls support a special version of the onchange event, which is raised when the control's value changes. For example, the **CheckBox** Web server control raises a change event when the user clicks the box. Events that occur often (and can be raised without the user knowing it), such as an onmouseover event, are not supported for server controls.

> **Note** Some server controls support a set of higher-level events. For example, the **Calendar** Web server control raises a **SelectionChanged** event that is a more abstract version of a **Click** event.

Event Arguments

Web and HTML server control events follow a standard .NET Framework pattern for event handler methods. All events pass two arguments: an object representing the object that raised the event, and an event object containing any event-specific information. The second argument is usually of type **System.EventArgs**, but for some controls is of a type specific to that control. For example, for an **ImageButton** Web server control, the second argument is of the type **ImageClickEventArgs**, which includes information about the coordinates where the user has clicked.

Postback and Non-Postback Events in Web Server Controls

In Web server controls, certain events, typically click events, cause the form to be posted back to the server. Change events in HTML server controls and Web server controls, such as the **TextBox** control, are captured but do not immediately cause a post. Instead, they are cached by the control until the next time a post occurs. Then, when the page is processed on the server again, all the pending events are raised and processed.

> **Note** If the browser supports it, validation controls can check user input using client script, without a round trip to the server. For details, see Introduction to Validating User Input in Web Forms.

During server page processing, events are processed first, in no particular order. When all change events have been processed, the click event that caused the form to be posted is processed.

> **Note** You should not create application logic that relies on the change events being raised in a specific order unless you have detailed knowledge of page event processing. For more information, see Postback Event Sample.

You can specify that a change event cause a form post. Web server controls that support a change event include an **AutoPostBack** property. When this property is **true**, the control's change event causes the form to post immediately, without waiting for a click event. For example, by default, a **CheckBox** control's **CheckedChanged** event does not cause the page to be submitted. However, by setting the control's **AutoPostBack** property to **true**, you specify that as soon as a user clicks the check box, the page is sent to the server for processing.

> **Note** For the **AutoPostBack** property to work properly, the user's browser must be set to allow scripting. This is the default in most cases. However, some users disable scripting for security reasons. For details, see ASP.NET Server Controls and Browser Capabilities.

Bubbled Events

Web server controls such as the **Repeater**, **DataList**, and **DataGrid** controls can contain button controls that themselves raise events. For example, each row in a **DataGrid** control can contain one or more buttons created dynamically by templates.

Rather than each button raising an event individually, events from the nested controls are *bubbled* — that is, they're sent to the container. The container in turn raises a generic event called **ItemCommand** with parameters that allow you to discover which individual control raised the original event. By responding to this single event, you can avoid having to write individual event handlers for child controls.

The **ItemCommand** event includes the two standard event arguments, an object referencing the source of the event and an event object containing event-specific information.

> **Note** The **DataGrid** and **DataList** Web server controls support additional events, such as **EditCommand**, **DeleteCommand**, and **UpdateCommand**, which are special cases of bubbled events.

With buttons, you can use the **CommandArgument** property to pass a user-specified string to the event handler to help you identify what button raised the event. For example, in a **DataList** control, buttons raise the **ItemCommand** event. You can set the **CommandArgument** property of each button to a different value — perhaps one button's value is "ShowDetails" and another button's value is "AddToShoppingCart" and then capture those values in the event handler later.

Event Delegates in Web Forms Pages

An event is a message — effectively, something like "a button has been clicked". In your application, you want the message to be translated into a method call in your code, such as "Button1_Click". The binding between the event message and a specific method — that is, an event handler — is done using an event delegate. For more information, see Events and Delegates.

In Web Forms pages, you typically do not need to explicitly code delegates. If you use the Web Forms Designer in Visual Studio, the designer generates code that automatically binds events to methods. In Visual Basic, this is done using the Handles keyword in the event handler declaration, as in this example:

```
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles MyB
ase.Load
```

In Visual C#, the designer generates an explicit event-handler delegate in the page, similar to the following:

```
private void InitializeComponent()
{
   this.Load += new System.EventHandler(this.Page_Load);
}
```

Alternatively, the ASP.NET page framework also supports an automatic way to associate page events and methods. If the **AutoEventWireup** attribute of the Page directive is set to **true** (or if it is missing, since by default it is **true**), the page framework calls page events automatically, specifically the **Page_Init** and **Page_Load** methods. In that case, no explicit **Handles** clause or delegate is needed.

The disadvantage of the **AutoEventWireup** attribute is that it requires that the page event handlers have specific, predictable names. This limits your flexibility in how you name your event handlers. Therefore, in Visual Studio, the **AutoEventWireup** attribute is set to **false** by default and the designer generates explicit code to bind page events to methods.

If you do set **AutoEventWireup** to **true**, Visual Studio will generate code to bind the events and the page framework will automatically call events based on their names. This can result in the same event code being called twice when the page runs. As a

consequence, you should always leave **AutoEventWireup** set to **false** when working in Visual Studio.

Responding to Both Client and Server Events in ASP.NET Server Controls

For the most part, you will be primarily interested in events that are raised in server code. However, if it is appropriate for your application, you can also handle client-side events for ASP.NET server controls by writing client script.

> **Note** You cannot use HTML syntax to bind to client-side events for Web server controls. Instead, you have to add event-binding attributes in code. For an example, see the table below.

For example, you might have an HTML image button element that you have converted to an HTML server control. Typically, in a Web Forms page you would handle the image button's click event in server code. However, you might also want to use client code to change the image when the user moves the mouse over it. You can do that by creating a client script for the image button's **onmouseover** event. (In this example, the assumption is that you are working with a browser that supports HTML 4.0, such as Microsoft Internet Explorer 4.0 or later.)

> **Note** In the case that both the client-side event handler and a server-side event handler have the same event-handler name, the client-side event handler always runs first, then the server event handler. However, it is confusing to allow this scenario, so some planning for a naming convention is strongly suggested.

Handling a Click Event in Client and Server Code

There is one event — the client onclick event — that introduces a difficulty if you want to handle it on both the client and the server. The problem arises because all button server controls (and other controls whose **AutoPostBack** property is set to **true**) submit the page to the server. However, in HTML, only a few controls inherently submit a form:

- The HTML submit button (`<INPUT type=submit>`), which is the HtmlInputButton control with its type set to **Submit** or **Image**. You can add this control from the HTML tab of the Toolbox.
- The **Button** Web server control (`<asp:button>`).

For all other controls that are specified to submit the page, a small client script is written into the page and called to submit the form when the control is clicked. Those controls therefore already use the client-side **OnClick** event to invoke this submit script.

You can create client-side **OnClick** handlers for all controls, but you need to choose the approach that works with each type of control. The following table summarizes the strategies you use for different types of controls.

Control	Strategy
HtmlInputButton, which includes HTML server control buttons whose type is set to Submit, Reset, or Image	Include an **onclick** attribute in the HTML syntax for the control: `<INPUT Type="Submit" Runat="Server" Value="caption" onclick="clientfunction()" ...>` On the server side, these types of buttons raise a ServerClick event instead of a simple **Click** event. The client event is raised first, and then the form is submitted and the server event is handled.
All other HTML controls (those that do not submit a form by default)	Include an **onclick** attribute in the HTML syntax for the control, but follow it with a semicolon (;): `<INPUT Type="Button" Runat="Server" Value="caption" onclick="clientfunction();" ...>` This causes your function to be called first, before the client-side submit script is called.
Web server controls, including buttons (`<asp:button>`) and other controls (for example, `<asp:checkbox>`)	You cannot specify a client-side event in the HTML syntax for a Web server control. Instead, add an event attribute to the control at run time in server code using code such as the following: `Button1.Attributes.Add("onclick", "clientfunction();")` **Note** For the **Button** Web server control, you do not need the semicolon, because that control automatically submits the page.

Application and Session Events

In addition to page and control events, the ASP.NET page framework provides ways for you to work with events that can be raised when your application starts or stops or when an individual user's session starts or stops:

- Application events are raised for all requests to an application. For example, **Application_BeginRequest** is raised when any Web Forms page or XML Web service in your application is requested. This event allows you to initialize resources that will be used for each request to the application. A corresponding event, **Application_EndRequest**, provides you with an opportunity to close or otherwise dispose of resources used for the request.
- Session events are similar to application events (there is a **Session_Start** and a **Session_End** event), but are raised with each unique session within the application. A session begins when a user requests a page for the first time from your application and ends either when your application explicitly closes the session or when the session times out.

You can create handlers for these types of events in the Global.asax file. For details, see Global.asax File and Global.asax Syntax.

See Also

Server Event Handling in Web Forms Pages | Global.asax File | Introduction to Web Forms State Management | Working with Httpapplication Instances

Creating Event Handlers in Web Forms Pages

Controls have a default event, which is the event most commonly associated with that control. For example, the default event for a button is the click event. You can create event handlers for both the default event and other events; however, the procedure is different for each type of event.

To create the event handler for a default event

- In Design view of the Web Forms Designer, double-click the control or page.

  The Code Editor opens with the insertion point in the event handler.

There is a different process for creating a handler for non-default events. The process differs for Visual Basic and Visual C#, due to slight differences in the Web Forms Designer user interface for those languages.

To create an event handler for non-default events in Visual Basic

1. Open or switch to the Code Editor for the page.
2. At the top of the window, select the control from the left-hand drop-down list, and select the event from the right-hand drop-down list.

   Note Events for which methods already exist are displayed in bold.

   The event handler is created.

   Visual Basic creates an event handler and adds it to your form's class.

To create an event handler for non-default events in Visual C#

1. In Design view, select the control, and then press F4 to display the Properties window.
2. In the Properties window, click the **Events** button ( ).

   The Properties window displays a list of the events for the control, with boxes to the right that display the names of event handlers bound to those events.

3. Locate the event you want to create a handler for and then:

   - In the event name box, type the name of an event handler.

   -or-

   - Double-click the event name box to create a handler whose name follows the convention *controlID_eventname*.

   The new event handler is created with the name you typed or with the generated name.

Binding to an Existing Event Handler in Web Forms Pages | Creating an Event Handler at Run Time in Web Forms Pages | Connecting Multiple Events to a Single Event Handler in Web Forms Pages | ASP.NET Server Control Event Model | Handling and Raising Events | Server Event Handling in Web Forms Pages | ASP.NET Server Controls

Binding to an Existing Event Handler in Web Forms Pages

If your page already contains an event-handling method, you can bind an event to it rather than creating a new handler. The process is slightly different for Visual Basic and Visual C#.

To bind to an existing event handler in Web Forms using Visual Basic

- Modify the event-handler declaration to include a Handles keyword specifying the event to bind to the method, as in the following example:

```
Sub MyEventHandler (ByVal sender as System.Object, ByVal e as System.EventArgs) Handles B
utton1.Click
```

> **Note** It is up to you to make sure that the method signature (the number and type of the method arguments) is appropriate for the event you want to bind to.

To bind to an existing event handler in Web Forms using Visual C#

1. In Design view, select the control whose event you want to bind to a method.
2. In the Properties window, click the **Events** button ( ).

   The Properties window displays a list of the events for the control, with boxes to the right that display the names of event handlers bound to those events.
3. From the drop-down list box, select the method to bind the event to. The methods displayed in the list are those that have the correct signature for the event you want to handle.

See Also

Creating Event Handlers in Web Forms Pages | Creating an Event Handler at Run Time in Web Forms Pages | Connecting Multiple Events to a Single Event Handler in Web Forms Pages | ASP.NET Server Control Event Model | Handles | Server Event Handling in Web Forms Pages | ASP.NET Server Controls | Event Handlers in Visual Basic and Visual C#

Creating an Event Handler at Run Time in Web Forms Pages

If you already have an event handler with the appropriate signature, you can bind a control event to it at run time.

To create an event handler at run-time in Web Forms using Visual Basic

- Include an AddHandler statement, passing it the event to bind and the address of the method to call. Be sure that the statement is executed before the event can be raised — typically, you add handlers in the page initialization. The following example shows how you can bind the **Click** event of the **Button1** control a method called `myEventHandler`:

```
AddHandler Button1.Click, AddressOf myEventHandler
```

To create an event handler at run-time in Web Forms using Visual C#

- Create an instance of the EventHandler delegate, passing it the address of the method to bind to. Then add the delegate object to the list of methods called when the event is raised. The following example shows how you can bind the **Click** event of the **Button1** control to a method called `myEventHandler`:

```
Button1.Click += new System.EventHandler(this.myEventHandler);
```

See Also

Creating Event Handlers in Web Forms Pages | Binding to an Existing Event Handler in Web Forms Pages | Connecting Multiple Events to a Single Event Handler in Web Forms Pages | ASP.NET Server Control Event Model | Handles | Server Event Handling in Web Forms Pages | ASP.NET Server Controls | Handling and Raising Events (.NET Framework documentation)

Connecting Multiple Events to a Single Event Handler in Web Forms Pages

If you already have an event handler, you can bind several control events to it. These multiple events can be from the same control or one event from several different controls (as long as the events all have the same signature). For example, you may want to bind the **Click** events of several **Button** Web server controls on a Web Forms page to a single event handler.

For both Visual Basic and Visual C#, you must add specific code to the event-handler method signature in the code-behind file.

To connect multiple events to a single event handler in Visual Basic

- Modify the Handles clause of a method by adding the names of the events that the method should handle. Separate the event names with commas.

  The following example shows how you can have the method `MyMultipleEventHandler` bound to events raised by three controls:

  ```
  Sub MyMultipleEventHandler (ByVal sender as System.Object, ByVal e as System.EventArgs) H
  andles Button1.Click, Button2.Click, Button3.Click
  ```

  Note It is up to you to make sure that the method has the correct signature for the event it is handling.

If you are using Visual C#, you associate multiple control events with a single event handler using the Web Forms Designer.

To connect multiple events to a single event handler in Visual C#

1. In Design view, select a control whose event you want to bind to a method.
2. In the Properties window, click the **Events** button ( ).

   The Properties window displays a list of the events for the control, with boxes to the right that display the names of event handlers bound to those events.
3. From the drop-down list, select the method to bind the event to. The methods displayed in the list are those that have the correct signature for the event you want to handle.

   The Code Editor opens, showing the method you selected. In addition, a line is added to the page's **InitializeComponent** method to perform the binding. The following shows an example of two button Click events that call the same handler:

   ```
   this.Button1.Click += new System.EventHandler(this.myEventHandler);
   this.Button2.Click += new System.EventHandler(this.myEventHandler);
   ```
4. Repeat Steps 1 through 3 for the next control whose event you want to bind to the method.

When your handler is called, you can determine which control caused the event.

To determine which control caused the event

1. In the event handler, declare a variable whose type matches the controls that raise the event.
2. Assign the `sender` argument of the event handler to the variable, casting it to the appropriate type.

   The following example shows the handler for a **Button**-control click event that is called by several different buttons. The handler displays the ID property of the button that caused the event.

   ```
   ' Visual Basic
   Private Sub Button1_Click(ByVal sender As System.Object, _
       ByVal e As System.EventArgs) _
       Handles Button1.Click, Button2.Click, Button3.Click
           Dim b As Button = CType(sender, Button)
           Label1.Text = b.ID
   End Sub
   ```

```
// C#
private void Button1_Click(object sender, System.EventArgs e)
    {
        Button b = (Button) sender;
        Label1.Text = b.ID;
    }
```

Page and Application Context in Web Forms Applications

When a Web application runs, ASP.NET maintains information about the current application, about each user session, the current HTTP request, the requested Web Forms page, and so on. The ASP.NET page framework contains a series of classes to encapsulate this context information.

ASP.NET makes instances of these classes available as intrinsic objects that you can access from your code. The following table lists these intrinsic objects and the classes they are instances of.

> **Note** Although the classes that define these objects are new with ASP.NET, the objects are used in the same way as with previous versions of ASP.

Object Name	Description	ASP.NET Class
Response	Provides access to the output stream for the current page. You can use this class to inject text into the page, write cookies, and more. For details, see Page.Response Property.	HttpResponse
Request	Provides access to the current page request, including the request headers, cookies, client certificate, query string, and so on. You can use this class to read what the browser has sent. For details, see Page.Request Property.	HttpRequest
Context	Provides access to the entire current context (including the request object). You can use this class to share information between pages.	HttpContext
Server	Exposes utility methods that you can use to transfer control between pages, get information about the most recent error, encode and decode HTML text, and more.	HttpServerUtility
Application	Provides access to application-wide methods and events for all sessions. Also provides access to an application-wide cache you can use to store information. For details, see Application State.	HttpApplicationState
Session	Provides information to the current user session. Also provides access to a session-wide cache you can use to store information, along with the means to control how the session is managed. For details, see Session State.	HttpSessionState
Trace	Provides a way to get both system and custom trace diagnostic messages to display in the HTTP page output. For details, see ASP.NET Trace.	TraceContext

The following topics show examples of how the intrinsic objects can be used.

Object	Example topics
Application	• Code: Reading Values From Application State (Visual Basic) • Code: Saving Values in Application State (Visual Basic)
Request	• Code: Reading a Cookie (Visual Basic) • Code: Retrieving the Client's Browser Information (Visual Basic) • Code: Writing a Cookie (Visual Basic)
Server	• Code: Encoding HTML Text (Visual Basic) • Code: Handling Application-Level Errors (Visual Basic) • Code: Handling Page-Level Errors (Visual Basic) • Code: Redirecting to Another Page in the Same Application (Visual Basic)

Redirecting Users to Another Page

You may want to redirect users from one Web Forms page to another page. You might do this to display a page that is matched to the user's browser capabilities or is written in the language that the user speaks.

There are two ways to redirect pages:

- Using a server-side method. In this scenario, the server simply transfers the context to another page. The advantage is that you can share page context information between pages. The disadvantage is that the user's browser does not know about the transfer, so the browser's history is not updated. If the user refreshes the page, unexpected results can occur.
- Using the browser. In this scenario, you send a command to the user's browser that causes the browser to fetch a different page. The advantage is that the browser's history is updated. The disadvantage is that this scenario performs an extra round trip, which can affect performance.

To redirect users to another page using a server-side method

- Call the Server.Transfer, passing it the name of the page to redirect to.
- The following example shows how to redirect to another page.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button1.Click
        Server.Transfer("Webform2.aspx")
    End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e)
{
   Server.Transfer("Webform2.aspx");
}
```

For details on sharing page context during a server transfer, see Passing Values Between Web Forms Pages.

To redirect users to another page from the browser

1. Set the **Response** object's BufferOutput property to **true**.
2. Call the **Response** object's Redirect method, passing it the URL of the page to redirect to.

   The following shows how to redirect based on the contents of a local variable, `UserLanguage`, that is set elsewhere.

```
' Visual Basic
Response.BufferOutput = True
If UserLanguage = "English" Then
   Response.Redirect("http://www.microsoft.com/gohere/look.htm")
ElseIf UserLanguage = "Deutsch" Then
   Response.Redirect("http://www.microsoft.com/gohere/look_deu.htm")
ElseIf UserLanguage = "Español" Then
   Response.Redirect("http://www.microsoft.com/gohere/look_esp.htm")
End If

// C#
Response.BufferOutput = true;
if (UserLanguage == "English")
{
   Response.Redirect("http://www.microsoft.com/gohere/look.htm");
}
else if (UserLanguage == "Deutsch")
{
   Response.Redirect("http://www.microsoft.com/gohere/look_deu.htm");
}
```

```
else if (UserLanguage == "Español")
{
   Response.Redirect("http://www.microsoft.com/gohere/look_esp.htm");
}
```

Detecting Browser Types in Web Forms

Different browsers, and different versions of the same browsers, support different features. In your application, you might need to determine what type of browser a user is viewing pages with, and perhaps even determine if the browser supports certain features.

> **Note** The ASP.NET page framework can automatically determine browser capabilities and use this information to render appropriate HTML elements and attributes for Web controls. For details, see ASP.NET Server Controls and Browser Capabilities.

Browsers and client devices are split into two distinctive groups: uplevel and downlevel. These groups define the type of native support a browser or client device offers, and they generally determine the presentation and behavior of a loading page from a Web server.

Browsers and client devices that are considered uplevel usually support at least the following:

- ECMAScript (JScript, JavaScript) version 1.2.
- HTML version 4.0
- The Microsoft Document Object Model (MSDOM)
- Cascading style sheets (CSS)

Downlevel browsers and client devices support the following only:

- HTML version 3.2

To detect browser types in Web Forms pages

- Query the HttpRequest.Browser property, which contains an HttpBrowserCapabilities object. This object gets information from the browser or client device during an HTTP request, telling your application the type and level of support the browser or client device offers.

  The following example shows how you can displays browser information the information in a text box on the page.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button1.Click
   Dim s As String = ""
   With Request.Browser
      s &= "Browser Capabilities" & vbCrLf
      s &= "Type = " & .Type & vbCrLf
      s &= "Name = " & .Browser & vbCrLf
      s &= "Version = " & .Version & vbCrLf
      s &= "Major Version = " & .MajorVersion & vbCrLf
      s &= "Minor Version = " & .MinorVersion & vbCrLf
      s &= "Platform = " & .Platform & vbCrLf
      s &= "Is Beta = " & .Beta & vbCrLf
      s &= "Is Crawler = " & .Crawler & vbCrLf
      s &= "Is AOL = " & .AOL & vbCrLf
      s &= "Is Win16 = " & .Win16 & vbCrLf
      s &= "Is Win32 = " & .Win32 & vbCrLf
      s &= "Supports Frames = " & .Frames & vbCrLf
      s &= "Supports Tables = " & .Tables & vbCrLf
      s &= "Supports Cookies = " & .Cookies & vbCrLf
      s &= "Supports VBScript = " & .VBScript & vbCrLf
      s &= "Supports JavaScript = " & .JavaScript & vbCrLf
      s &= "Supports Java Applets = " & .JavaApplets & vbCrLf
      s &= "Supports ActiveX Controls = " & .ActiveXControls & vbCrLf
   End With
   TextBox1.Text = s
End Sub
```

```
// C#
private void Button1_Click(object sender, System.EventArgs e)
{
   System.Web.HttpBrowserCapabilities browser = Request.Browser;
   string s = "Browser Capabilities\n"
      + "Type = "                     + browser.Type + "\n"
      + "Name = "                     + browser.Browser + "\n"
      + "Version = "                  + browser.Version + "\n"
      + "Major Version = "            + browser.MajorVersion + "\n"
      + "Minor Version = "            + browser.MinorVersion + "\n"
      + "Platform = "                 + browser.Platform + "\n"
      + "Is Beta = "                  + browser.Beta + "\n"
      + "Is Crawler = "               + browser.Crawler + "\n"
      + "Is AOL = "                   + browser.AOL + "\n"
      + "Is Win16 = "                 + browser.Win16 + "\n"
      + "Is Win32 = "                 + browser.Win32 + "\n"
      + "Supports Frames = "          + browser.Frames + "\n"
      + "Supports Tables = "          + browser.Tables + "\n"
      + "Supports Cookies = "         + browser.Cookies + "\n"
      + "Supports VBScript = "        + browser.VBScript + "\n"
      + "Supports JavaScript = "      + browser.JavaScript + "\n"
      + "Supports Java Applets = "    + browser.JavaApplets + "\n"
      + "Supports ActiveX Controls = " + browser.ActiveXControls + "\n";
   TextBox1.Text = s;
}
```

Web Forms State Management

Web Forms pages and the ASP.NET page framework use HTTP to communicate between browser or client device and the Web server. HTTP is a stateless protocol, meaning that it does not automatically indicate whether the requests in a sequence are all from the same client or even whether a single browser instance is still actively viewing a page or site. In addition, each time a page is processed in a round trip, it is destroyed and rendered anew, and all information about the state of the Web Forms page and the controls on that page are lost.

As a result, building Web applications that need to maintain cross-request state information — for example, showing a shopping cart or paging through data — can be extremely challenging without additional infrastructure help.

The following topics provide a general background and how-to information on how you can manage state in your Web Forms pages.

In This Section

Introduction to Web Forms State Management
Provides an overview of how values are preserved in a Web Forms page during round trips to the server.
State Management Recommendations
Provides an overview of the advantages and disadvantages of state management techniques available in ASP.NET.
Saving Web Forms Page Values Using View State
Provides information on how to store information in view state (in the page) between round trips.
Passing Values Between Web Forms Pages
Describes how to redirect one Web Forms page to another and pass information to the target page.

Introduction to Web Forms State Management

Web pages are recreated each time the page is posted to the server. In traditional Web programming, this would ordinarily mean that all information associated with the page and the controls on the page would be lost with each round trip. For example, if a user enters information into a text box, that information would be lost in the round trip from the browser or client device to the server. For more information, see Web Forms Page Processing.

To overcome this inherent limitation of traditional Web programming, the ASP.NET page framework includes various options to help you preserve changes — that is, for managing state. The page framework includes a facility called *view state* that automatically preserves property values of the page and all the controls on it between round trips. However, you will probably also have application-specific values that you want to preserve. To do so, you can use one of the state management options.

Some of the options involve keeping information on the client — for example, directly in the page or in a cookie — and others involve storing information on the server between round trips. Each option has distinct advantages and disadvantages.

Client-Based State Management Options

The following sections describe options for state management that involve storing information either in the page or on the client computer. For these options, no information is maintained on the server between round trips.

View State

The Control.ViewState property provides a dictionary object for retaining values between multiple requests for the same page. This is the method that the page uses to preserve page and control property values between round trips.

When the page is processed, the current state of the page and controls is hashed into a string and saved in the page as a hidden field. When the page is posted back to the server, the page parses the view state string at page initialization and restores property information in the page.

You can store values in view state as well. For details, see Saving Web Forms Page Values Using View State. For recommendations on when to use view state, see State Management Recommendations.

Hidden Form Fields

ASP.NET allows you to use HTML-standard hidden fields in a form. A hidden field does not render visibly in the browser, but you can set its properties just as you can with a standard control. When a page is submitted to the server, the content of a hidden field is sent in the HTTP Form collection along with the values of other controls. A hidden field acts as a repository for any page-specific information that you would like to store directly in the page.

> **Security Note** It is easy for a malicious user to see and modify the contents of a hidden field. Do not store any information in a hidden field that is sensitive or that your application relies on to work properly.

A hidden field stores a single variable in its value property and must be explicitly added to the page. Then you insert your value into the hidden field. ASP.NET provides the **HtmlInputHidden** control that offers hidden field functionality. For more information see ASP.NET Server Controls by Function.

In order for hidden field values to be available during page processing, you must submit the page using an HTTP post method. That is, you cannot take advantage of hidden fields if a page is processed in response to a link or HTTP GET method. For usage recommendations, see State Management Recommendations.

Cookies

A cookie is a small amount of data stored either in a text file on the client's file system or in-memory in the client browser session. It contains page-specific information the server sends to the client along with page output. Cookies can be temporary (with specific expiration times and dates) or persistent.

You can use cookies to store information about a particular client, session, or application. The cookies are saved on the client device, and when the browser requests a page, it sends the information in the cookie along with the request information. The server can read the cookie and extract its value. A typical use is to store a token (perhaps encrypted) indicating that the user has already been authenticated in your application.

> **Security Note** The browser can only send the data back to the server that originally created the cookie. However, malicious users have ways to "steal" cookies and read their contents. It is recommended that you do not store sensitive information in a cookie, such as a user name or password. Instead, store a token that you can use to look up the sensitive information on the server.

For more information on using cookies, see HttpResponse.Cookies Property and State Management Recommendations.

Query Strings

A query string is information appended to the end of a page's URL. A typical example might look like the following:

```
http://www.contoso.com/listwidgets.aspx?category=basic&price=100
```

In the URL path above, the query string starts with the question mark (?) and includes two attribute-value pairs, one called "category" and the other called "price."

Query strings provide a simple but limited way of maintaining some state information. For example, they are an easy way to pass information from one page to another, such as passing a product number from one page to another page where it will be processed. However, most browsers and client devices impose a 255-character limit on the length of the URL.

> **Security Note** Information passed in a query string can be tampered with by a malicious user. Do not rely on query strings to convey important or sensitive data. For more information, see Scripting Exploits.

In order for query string values to be available during page processing, you must submit the page using an HTTP get method. That is, you cannot take advantage of a query string if a page is processed in response to an HTTP post method. For usage recommendations, see State Management Recommendations.

Server-Based State Management Options

ASP.NET offers you a variety of ways to maintain state information on the server, as described in the following sections.

Application State

ASP.NET allows you to save values using application state (an instance of the HttpApplicationState class) for each active Web application. Application state is a global storage mechanism accessible from all pages in the Web application and is thus useful for storing information that needs to be maintained between server round trips and between pages. For more information, see Application State.

Application state is a key-value dictionary structure created during each request to a specific URL. You can add your application-specific information to this structure to store it between page requests.

Once you add your application-specific information to application state, the server manages it. For usage recommendations, see State Management Recommendations.

Session State

ASP.NET allows you to save values using session state, which is an instance of the HttpSessionState class for each active Web application session. (For an overview, see Session State.)

Session state is similar to application state, except that it is scoped to the current browser session. If different users are using your application, each will have a different session state. In addition, if the same user leaves your application and then returns later, that user will also have a different session state.

Session state is structured as a key-value dictionary structure for storing session-specific information that needs to be maintained between server round trips and between requests for pages. For more information, see Session State.

Session state enables you to:

- Uniquely identify browser or client-device requests and map them to an individual session instance on the server.
- Store session-specific data on the server for use across multiple browser or client-device requests within the same session.
- Raise appropriate session management events. In addition, you can write application code leveraging these events.

Once you add your application-specific information to session state , the server manages this object. Depending on what options you specify, session information can be stored in cookies, an out-of-process server, or a SQL Server. For usage recommendations, see State Management Recommendations.

Database Support

Maintaining state using database technology is a common practice when storing user-specific information where the information store is large. Database storage is particularly useful for maintaining long-term state or state that must be preserved even if the server must be restarted.

The database approach is often used in conjunction with cookies. For example, when a user first accesses your application, you might have the user log in. You can look up the user in your database and then pass a cookie to the user. The cookie might contain only the ID of the user in your database (for example, a customer number). You can then use the cookie in subsequent requests to find the user information in the database as needed.

> **Security Note** Because cookies can be tampered with, you should use caution in using them to store information that your application relies on. For example, never store sensitive information in a cookie. If you use cookies to store tokens (such as a user ID), consider encrypting the cookie value or adding logic to be sure that the cookie's value has not been tampered with.

The database support approach enables you to:

- Uniquely identify browser or client-device requests and map them to a unique ID.
- Maintain state by relating stored information to the unique ID. You can use the unique ID to query the database for information relating to that ID. You can then modify the information and save it back to the database for use across multiple requests for the same — or different — pages in your site.
- Raise appropriate events. A condition in the database may determine site action. For example, if the user of a commerce site attempts to purchase something that is not in stock, a database query may signal that the Web site should prompt the user to make another selection.

For more information on using a database to maintain state, see State Management Recommendations.

State Management Recommendations

State management is the process by which you maintain state and page information over multiple requests for the same or different pages. As is true for any HTTP-based technology, Web Forms pages are stateless, which means that they do not automatically indicate whether the requests in a sequence are all from the same client or even whether a single browser instance is still actively viewing a page or site. Furthermore, pages are destroyed and recreated with each round trip to the server; therefore page information will not exist beyond the life cycle of a single page. For more information on server round trips and the Web Forms page life cycle, see Web Forms Page Processing.

ASP.NET provides multiple ways to maintain state between server round trips. Choosing among the options for state management available in ASP.NET will depend heavily upon your application, and it should be based on the following criteria:

- How much information do you need to store?
- Does the client accept persistent or in-memory cookies?
- Do you want to store the information on the client or server?
- Is the information sensitive?
- What sorts of performance criteria do you have for your application?

ASP.NET supports various client-side and server-side options for state management.

Client-side options are:

- The **ViewState** property
- Hidden fields
- Cookies
- Query strings

Server-side options are:

- Application state
- Session state
- Database

Client-Side State Management Options

Storing page information using client-side options doesn't use server resources. These options tend to have minimal security but fast server performance because the demand on server resources is modest. However, because you must send information to the client for it to be stored, there is a practical limit on how much information you can store this way.

View State

Web Forms pages provide the **ViewState** property as a built-in structure for automatically retaining values between multiple requests for the same page. View state is maintained as a hidden field in the page. For more information see Introduction to Web Forms State Management.

You can use view state to store your own page-specific values across round trips when the page posts back to itself. For example, if your application is maintaining user-specific information — that is, information used in the page but not necessarily part of any control — you can store it in view state.

The advantages of using view state are:

- No server resources required. The view state is contained in a structure within the page code.
- Simple implementation.
- Automatic retention of page and control state.
- Enhanced security features. The values in view state are hashed, compressed, and encoded for Unicode implementations, thus representing a higher state of security than hidden fields have.

The disadvantages of using the view state are:

- Performance. Because the view state is stored in the page itself, storing large values can cause the page to slow down when users display it and when they post it.

- Security. The view state is stored in a hidden field on the page. Although view state stores data in a hashed format, it can be tampered with. The information in the hidden field can be seen if the page output source is viewed directly, creating a potential security issue. For more information see Introduction to Web Application Security.

For more information on using view state, see Saving Web Forms Page Values Using View State.

Hidden Fields

You can store page-specific information in a hidden field on your page as a way of maintaining the state of your page. For more information on hidden fields see Introduction to Web Forms State Management.

If you use hidden fields, it is best to store only small amounts of frequently changed data on the client. ASP.NET provides the **HtmlInputHidden** control, which offers hidden field functionality. For more information on **HtmlInputHidden** see ASP.NET Server Controls by Function.

> **Note** If you use hidden fields you must submit your pages to the server using the HTTP POST method rather than requesting the page via the page URL (the HTTP GET method).

The advantages of using hidden fields are:

- No server resources are required. The hidden field is stored and read from the page.
- Broad support. Almost all browsers and client devices support forms with hidden fields.
- Simple implementation.

The disadvantages of using hidden fields are:

- Security. The hidden field can be tampered with. The information in the hidden field can be seen if the page output source is viewed directly, creating a potential security issue. For more information see Introduction to Web Application Security.
- Limited storage structure. The hidden field does not support rich structures. Hidden fields offer a single value field in which to place information. To store multiple values, you must implement delimited strings and the code to parse those strings.
- Performance. Because hidden fields are stored in the page itself, storing large values can cause the page to slow down when users display it and when they post it.

Cookies

Cookies are useful for storing small amounts of frequently changed information on the client. The information is sent with the request to the server.

The advantages of using cookies are:

- No server resources are required. The cookie is stored on the client and read by the server after a post.
- Simplicity. The cookie is a lightweight, text-based structure with simple key-value pairs.
- Configurable expiration. The cookie can expire when the browser session ends, or it can exist indefinitely on the client computer, subject to the expiration rules on the client.

The disadvantages of using cookies are:

- Limited size. Most browsers place a 4096-byte limit on the size of a cookie, although the support for 8192-byte cookie size is becoming common in the new browser and client-device versions available today.
- User-configured refusal. Some users disable their browser or client device's ability to receive cookies, thereby limiting this functionality.
- Security. Cookies are subject to tampering. Users can manipulate cookies on their computer, which can potentially represent a security compromise or cause the application dependent on the cookie to fail. For more information see Introduction to Web Application Security.
- Durability. The durability of the cookie on a client computer is subject to cookie expiration processes on the client and user intervention.

> **Note** Cookies are often used for personalization, where content is customized for a known user. In most of these cases, identification is the issue rather than authentication, so it is enough to merely store the user name, account name, or a unique user ID (such as a GUID) in a cookie and use it to access the user personalization infrastructure of a site.

For details about creating and reading cookies, see HttpResponse.Cookies Property and HttpRequest.Cookies Property.

Query Strings

A query string is information appended to the end of a page's URL. For more information, see Introduction to Web Forms State Management.

You can use a query string to submit data back to your page or to another page through the URL. Query strings provide a simple but limited way of maintaining some state information. For example, they are an easy way to pass information from one page to another, such as passing a product number to another page where it will be processed.

> **Note** Query strings are a viable option only when a page is requested via its URL. You cannot read a query string from a page that has been submitted to the server.

The advantages of using query strings are:

- No server resources required. The query string is contained in the HTTP request for a specific URL.
- Broad support. Almost all browsers and client devices support passing values in a query string.
- Simple implementation. ASP.NET provides full support for the query string method, including methods of reading query strings using the HttpRequest.Params property.

The disadvantages of using query strings are:

- Security. The information in the query string is directly visible to the user via the browser user interface. The query values are exposed to the Internet via the URL so in some cases security may be an issue. For more information on see Introduction to Web Application Security.
- Limited capacity. Most browsers and client devices impose a 255-character limit on URL length.

Client-Side Method State Management Summary

The following table summarizes client-side state management options and when you should consider using them.

Method	Use when
View state	You need to store small amounts of information for a page that will post back to itself. Use of the **ViewState** property provides functionality with basic security.
Hidden fields	You need to store small amounts of information for a page that will post back to itself or another page, and security is not an issue. **Note** You can use a hidden field only on pages that are submitted to the server.
Cookies	You need to store small amounts of information on the client and security is not an issue.
Query string	You are transferring small amounts of information from one page to another and security is not an issue. **Note** You can use query strings only if you are requesting the same page, or another page via a link.

Server-Side State Management Options

Server-side options for storing page information tend to have higher security than client-side options, but they can use more Web server resources, which may lead to scalability issues when the size of the information store is large. ASP.NET provides several options to implement server-side state management. For more information, see Introduction to Web Forms State Management.

Application State

ASP.NET provides application state via the HttpApplicationState class as a method of storing global application-specific information that is visible to the entire application. Application state variables are, in effect, global variables for an ASP.NET application. For more information, see Application State.

You can store your application-specific values in application state, which is then managed by the server. For more information, see Introduction to Web Forms State Management.

The ideal data to insert into application state variables is data that is shared by multiple sessions and does not change often.

> **Note** If you store a dataset in application state, you have to cast it from **Object** back to a dataset. For details, see

Web Data Access Strategy Recommendations.

The advantages of using application state are:

- Ease of implementation. Application state is easy to use, familiar to ASP developers, and consistent with other .NET Framework classes.
- Global scope. Because application state is accessible to all pages in an application, storing information in application state can mean keeping only a single copy of the information (for instance, as opposed to keeping copies of information in session state or in individual pages).

The disadvantages of using application state are:

- Global scope. The global nature of application state can also be a disadvantage. Variables stored in application state are global only to the particular process the application is running in, and each application process can have different values. Therefore, you cannot rely on application state to store unique values or update global counters in Web-garden and Web-farm configurations.
- Durability. Because global data stored in application state is volatile, it will be lost if the Web server process containing it is destroyed, most likely from a server crash, upgrade, or shutdown.
- Resource requirements. Application state requires server memory, which can affect the performance of the server as well as the scalability of the application.

Careful design and implementation of application state can increase Web application performance. For example, placing a commonly used, relatively static dataset in application state can increase site performance by reducing the overall number of data requests to a database. However, there is a performance trade-off. Application state variables containing large blocks of information reduce Web server performance as server load increases. The memory occupied by a variable stored in application state is not released until the value is either removed or replaced. Therefore, it is best to use application state variables only with small, infrequently changed datasets. For more information on optimizing ASP.NET Web applications, see ASP.NET Optimization.

Session State

ASP.NET provides a session state, available as the HttpSessionState class, as a method of storing session-specific information that is visible within the session only. For more information, see Introduction to Web Forms State Management and Session State.

You can store your session-specific values and objects in session state, which is then managed by the server and available to the browser or client device. The ideal data to store in session-state variables is short-lived, sensitive data that is specific to an individual session.

> **Note** If you store a dataset in application state, you have to cast it from **Object** back to a dataset. See Web Data Access Strategy Recommendations.

The advantages of using session state are:

- Ease of implementation. The session state facility is easy to use, familiar to ASP developers, and consistent with other .NET Framework classes.
- Session-specific events. Session management events can be raised and used by your application.
- Durability. Data placed in session-state variables can survive Internet Information Services (IIS) restarts and worker-process restarts without losing session data because the data is stored in another process space.
- Platform scalability. Session state can be used in both multi-computer and multi-process configurations, therefore optimizing scalability scenarios.
- Session state works with browsers that do not support HTTP cookies, although session state is most commonly used with cookies to provide user identification facilities to a Web application. For more information on using session state without cookies, see ASP.NET Configuration Sections.

For more information, see Session State.

The disadvantage of using session state is:

- Performance. Session state variables stay in memory until they are either removed or replaced, and therefore can degrade server performance. Session state variables containing blocks of information like large datasets can adversely affect Web server performance as server load increases.

Database Support

In some cases, you may wish to use database support to maintain state on your Web site. Typically, database support is used in conjunction with cookies or session state. For example, it is quite common for an e-commerce Web site to maintain state information using a relational database for the following reasons:

- Security
- Personalization
- Consistency
- Data mining

The following are typical features of a cookie-supported database Web site:

- **Security**. The visitor types an account name and password into a site logon page. The site infrastructure queries the database with the logon values to determine if the user has rights to utilize your site. If the database validates the user information, the Web site will distribute a valid cookie containing a unique ID for that user on that client computer. The site grants access to the user.
- **Personalization**. With security information in place, your site is able to distinguish each user on your site by reading the cookie on the client computer. Typically, sites have information in the database that describes the preferences of a user (identified by a unique ID). This relationship is known as personalization. The site can research the user's preferences using the unique ID contained in the cookie, and then place content and information in front of the user that pertains to the user's specific wishes and reacts to the user's preferences over time.
- **Consistency**. If you have created a commerce Web site, you may wish to keep transactional records of purchases made for goods and services on your site. This information can be reliably saved in your database and referenced by the user's unique ID. It can be used to determine if a purchase transaction has been completed, and also to determine the course of action should a purchase transaction fail. The information may also be used to inform the user of the status of an order placed using your site.
- **Data mining**. Information about your site usage, your visitors, or your product transactions can be reliably stored in your database. For example, your business development department may wish to use this data collected from your site to determine next year's product line or distribution policy. Your marketing department may wish to examine demographic information about users on your site. Your engineering and support department may wish to look at transactions and note areas where your purchasing process could be improved. Most enterprise-level relational databases such as Microsoft SQL Server contain an expansive toolset for most data mining projects.

By designing the Web site to repeatedly query the database by using the unique ID during each general stage in the above scenario, the site maintains state. In this way, the user perceives that the site is remembering and reacting to him or her personally.

The advantages of using a database to maintain state are:

- Security. Access to databases is typically very secure, requiring rigorous authentication and authorization.
- Capacity. You can store as much information as you like in a database.
- Persistence. Database information can be stored as long as you like, and it is not subject to the availability of the Web server.
- Robustness and data integrity. Databases include various facilities for maintaining good data, including triggers and referential integrity, transactions, and so on. By keeping information about transactions in a database (rather than in session state, for example), you can recover from errors more readily.
- Accessibility. The data stored in your database is accessible to a wide variety of information-processing tools.
- Wide support. There is a large range of database tools available, and many custom configurations are available.

The disadvantages of using a database to maintain state are:

- Complexity. Using a database to support state management implies more complex hardware and software configurations.
- Performance. Poor construction of the relational data model can lead to scaling issues. Also, leveraging too many queries to the database can adversely affect server performance.

Server-Side Method State Management Summary

The following table summarizes server-side state management options and when you should consider using them.

Method	Use when
Application state	You are storing infrequently changed, global information that is used by many users, and security is not an issue. Do not store large quantities of information in application state.
Session state	You are storing short-lived information that is specific to an individual session, and security is an issue. Do not store large quantities of information in session state. Be aware that a session state object will be created and maintained for the lifetime of every session in your application. In applications hosting many users, this can occupy significant server resources and affect scalability.
Database support	You are storing large amounts of information, managing transactions, or the information must survive application and session restarts. Data mining is a concern, and security is an issue.

Saving Web Forms Page Values Using View State

Each control on a Web Forms page, including the page itself, has a **ViewState** property that it inherits from the base **Control** class. View state is used by the ASP.NET page framework to automatically save the values of the page and of each control just prior to rendering to the page. When the page is posted, one of the first tasks performed by page processing is to restore view state.

You can use the **ViewState** property to save your values independent of control state between round trips to the server. The **ViewState** property is stored in the page in a hidden form field.

> **Note** In order to use the **ViewState** property, your form must have a server form element (<form runat="server">). For usage recommendations, see State Management Recommendations.

To store information in view state

- Create and store a new element in the ViewState property.

  > **Note** The data must be in a format compatible with view state. For example, to store a dataset in view state, you should first convert it to a string representation.

```
' Visual Basic
ViewState("color") = "yellow"

// C#
ViewState["color"] = "red";
```

To retrieve information from view state

- Get the value of an element by specifying its name. Cast the object in view state to the type that you need it to be.

  The following example shows how you can retrieve a value stored earlier under the **ViewState** name "color." Note that the value is cast to a string.

```
' Visual Basic
Dim strColor as String
strColor = CStr(ViewState("color"))

// C#
string strColor;
strColor =(string)ViewState["color"];
```

The following example shows you can save a dataset in view state and then retrieve it. To save it, you create a string representation of it using the dataset's DataSet.WriteXml method. When retrieving the dataset, you cast it to a StringReader class and then call the dataset's DataSet.ReadXml method.

```
' Visual Basic
If Page.IsPostBack Then
   Dim sr as New System.IO.StringReader(CStr(ViewState("dsCustomers")))
   DsCustomers1.ReadXml(sr)
Else
   SqlDataAdapter1.Fill(DsCustomers1)
   Dim sw as New System.IO.StringWriter()
   DsCustomers1.WriteXml(sw)
   ViewState("dsCustomers") = sw.ToString()
End If

// C#
if (Page.IsPostBack)
{
   System.IO.StringReader sr = new System.IO.StringReader((string)(ViewState["dsCustomers"]))
```

```
;
   dsCustomers1.ReadXml(sr);
}
else
{
   sqlDataAdapter1.Fill(dsCustomers1);
   System.IO.StringWriter sw = new System.IO.StringWriter();
   dsCustomers1.WriteXml(sw);
   ViewState["dsCustomers"] = sw.ToString();
}
```

Passing Values Between Web Forms Pages

There are many times when you will want to navigate from one page to another and pass values from the first page to the second. For example, you might have a page that prompts users for a name and password. When users submit the form, you want to call another page that authenticates the user.

There are a variety of ways to share information between pages:

- Use a query string, which appends information onto the URL and passes it to the next page. This has the disadvantage of making the information visible. For details, see WebClient.QueryString Property and HttpRequest.QueryString Property.
- Use Session state to store information that is then accessible globally to all pages in the user's current session. However, this takes server memory and the information is stored until the session expires, which can represent more overhead than you want when you are simply passing information to the next page. For details, see Web Forms State Management.
- Use custom page properties and then redirect from the original page to the target page in a way that you can still read values in the old page. This strategy is described in this topic.

Web Forms pages are classes in your application, and as such, you can create properties for them as you would any class. However, Web Forms pages have a very short lifetime, since they effectively exist only long enough to perform page processing. Properties on a Web Forms page therefore have limited use, since they exist only while the page is being processed. But if you transfer control from one page to another using specific techniques, the second page can still access properties on the first page.

To create shareable values on the source page

1. In code, declare one or more read-only properties on the page using standard syntax for properties. Return the property value you want to pass to the next page.

   The following example shows how you can declare a property called `Property1` and sets its value to the value of text box on the page:

   ```
   ' Visual Basic
   Public ReadOnly Property Property1() As String
      Get
         Return TextBox1.Text
      End Get
   End Property

   // C#
   public string Property1
   {
      get
      {
         return TextBox1.Text;
      }
   }
   ```

2. Call the next page by calling the Transfer method of the `Server` object (the HttpServerUtility class), passing it the URL of the page you want to pass information to.

   The following example shows how you might call a page called `WebForm2` (in the same project) from an event handler:

   ```
   ' Visual Basic
   Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
   dles Button1.Click
           Server.Transfer("Webform2.aspx")
       End Sub

   // C#
   private void Button1_Click(object sender, System.EventArgs e)
   {
      Server.Transfer("Webform2.aspx");
   ```

```
}
```

To get the property values of the first page from the called page, create an instance variable of the source page class. You then assign to it the HTTP object (an instance of the IHttpHandler class), the object that received the original request.

To read property values from the source page in the called page

1. Create a global instance variable that is typed to the class of the source page.

   The following example shows how to declare a variable called `sourcepage` that is of the type `WebForm1`:

```
' Visual Basic
' Put immediately after the Inherits statements
' at the top of the file
Public sourcepage As WebForm1

// C#
// Put immediately after the opening brace of the class
public class WebForm3 : System.Web.UI.Page
    {
        public WebForm1 sourcepage;
        // etc.
```

2. In the **Page_Load** handler, get the source page from the **Context.Handler** object (IHttpHandler interface) and assign it to the variable that you created in step 1. You must cast the handler object to the type of the source page class.

   Note You should only perform this logic the first time the page runs (that is, when the page is first called from the source page).

3. Get the property values from the source page and use them as you would any object properties.

   Note Be sure to save the property values (for example, in view state) if you want to use them in page processing other than the first page initialization. For details, see Introduction to Web Forms State Management.

   The complete **Page_Load** handler might look like this:

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
MyBase.Load
   If Not Page.IsPostBack Then
      sourcepage = CType(Context.Handler, WebForm1)
      Label1.Text = sourcepage.Property1
   End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   if (!IsPostBack){
      WebForm1 sourcepage = (WebForm1) Context.Handler;
      Label1.Text = sourcepage.Property1;
   }
}
```

Data Access in Web Forms Pages

Many Web Forms pages involve data access — displaying data and, in some cases, allowing users to edit and update data. Knowledge of data access technology in Web Forms pages helps you create efficient Web applications.

The following sections contain introductory information on data access in Web Forms pages and on how to bind controls to data in a page.

> **Note** When you deploy an application that includes Visual Studio data-access components, you must make sure that the user installing the application has version 2.6 or higher of the Microsoft Data Access Components (MDAC). For more information, see Adding a Launch Condition for Microsoft Data Access Components.

In This Section

Introduction to Data Access in Web Forms Pages
Provides background on how data access works in Web Forms pages.
Data Sources for Web Forms Pages
Discusses what types of data you can work with in a Web Forms page.
Web Data Access Strategy Recommendations
Provides guidelines for choosing whether to use direct access to a data source or a disconnected cache (dataset); and if you use a dataset, whether to store it between round trips.
Data Walkthroughs for Web Forms Pages
Provides a list of Help topics that demonstrate various data access strategies for Web applications.
Web Forms Data Binding
Provides links to topics that discuss how data binding works in Web Forms pages and how to specify data binding for various types of controls.

Introduction to Data Access in Web Forms Pages

Web Forms pages often need to display information that derives from a database, an XML document or stream, or some other data source. The architecture of Web Forms pages provides you with ways to incorporate data sources (or references to them) in the page, to bind controls to data, and to manipulate data in various ways.

However, due to the nature of not just Web Forms pages, but of Web programming itself, data access in Web Forms pages differs in several ways from data access in Windows Forms or in forms technology of previous Microsoft products. To some extent, these are the same differences that make any kind of Web programming different from traditional forms programming: state management, separation of server and client, designing for scalability, and so on. In addition, because you are working with other resources such as databases, there are important points to understand about how to manage data in Web Forms pages.

> **Note** When you deploy an application that includes Visual Studio data-access components, you must make sure that the user installing the application has version 2.6 or higher of the Microsoft Data Access Components (MDAC). For more information, see Adding a Launch Condition for Microsoft Data Access Components.

Fundamentals of Data Access in Web Forms Pages

Data access in Web Forms pages is built around the following fundamental principles:

- Using a disconnected model
- Reading data more often than updating it
- Minimizing server resource requirements
- Accessing data using remote processes (distributing data access)

Disconnected Model

Web Forms pages are disconnected. Each time a Web Forms page is requested, it is built, processed, sent to the browser, and discarded from server memory. By extension, the same applies to data access in a Web Forms page. Data is read or updated while the page is being processed on the server; when the page is finished and sent to the browser, data is discarded along with other page elements.

This model has various implications for how you work with data in the Web Forms page:

- The data you are working with is not automatically available for each round trip — that is, when users click a button in the page. If you want to access the data again each time the page is posted to the server, you must either re-read the data from the source with each round trip or you must include code in the page to explicitly save it and restore it as part of page processing.
- It is impractical to maintain open connections to data sources. Generally, during page processing you open a connection to the source, read or write data, and then close the connection.
- During each round trip, you typically perform a single data access operation. For example, the first time the page is called, you might read data from the source and bind controls on the page to it. When users click a button, you might write data from a control back to a data source. If you are implementing operations such as paging in a grid, each round trip typically fetches one set of records.

Reading and Updating Data

The Web Forms data model presumes that most data access by Web pages is read-only. Typical examples are catalog or search listings, which display data items. (The items are often links to other pages.) In most cases, the user does not enter data that is written back to the data source.

Because most data access is read-only, the Web Forms data-binding architecture is one-way. That is, data binding displays data in controls, but does not write data from the controls to a data source.

One-way data binding makes Web Forms pages more efficient. Updating requires substantially more overhead in a page: the page must have available copies of the records to update and must include logic to update, insert, and delete records. Because this overhead can add significantly to the page processing time and to server memory requirements, and because in most pages no updates are required, the default for Web Forms pages is not to include a way to write data from a control to a data source.

If you are creating a page that updates a data source, you can include the logic yourself to perform the update operations. For example, a portal page might allow users to specify custom display options. You can use a Web Forms page to present available options and then write the user's options to a database. For details about updating, see Dataset Updates in Visual Studio .NET. For an example of how to perform updates, see Walkthrough: Updating Data Using a Database Update Query in Web Forms.

Minimizing Use of Server Resources

Because Web Forms pages are processed on the server before being sent to the browser, any data access in the page adds to the server load in both processing time and memory usage. If you choose to save data between round trips and you keep it on the server, you use server resources even when the page is not being processed.

Data access in Web Forms pages therefore requires careful attention to how you are using resources. A data–access design that uses server memory or processing time unnecessarily might work for a few users of your Web application, but can become unwieldy as your application scales up to many users. Examples of some of the design decisions you might make include:

- Get only as much data from a data source as you need in any given page.
- Use client-side state management options (for example, view state) to store data if possible.

For more details about designing data access for Web Forms pages, see Web Data Access Strategy Recommendations.

Data Access in Remote Processes

Web Forms pages are the presentation tier of your Web application. You can build data access into your pages, but it is also common to separate data access logic from the UI by building it into another component (for example, an XML Web service) that interacts with the data source. For more information, see Introduction to ASP.NET Web Applications in Visual Studio.

As .NET components, Web Forms pages exchange data with other processes via an XML stream. You generally do not need to work directly with the XML being passed between components. The data framework of your page (usually a dataset) performs this conversion automatically. However, if it makes sense in your application to do so, you can access data in XML format directly.

Access Permissions for Web Applications

Regardless of the specific data-access strategy you select for your application, you need to be aware of the security implications of data access. In most cases, data resources are protected by Windows or database-specific security. When you create data access in your application, you need to be sure that the application will have sufficient permissions at run time to get access to the data it needs. (The permissions that your application has at run time are often different from the access you have at design time while creating and testing your application.)

For details, see Access Permissions for Web Applications. For details about accessing SQL Server, see Accessing SQL Server from a Web Application.

Data Sources for Web Forms Pages

The Web Forms page architecture provides a very flexible notion of data. This includes everything from traditional database access, to using XML documents as a data source, to generating data at run time and storing it in an array.

Database Access

To read and write database data, you use ADO.NET. ADO.NET includes managed data providers (connection and command objects) to communicate with SQL Server or OLE DB-compatible databases. ADO.NET also includes support for disconnected data access via a dataset, which is an in-memory cache into which you can read records to work with. For details, see Introduction to Datasets.

> **Note** You need to be sure that when your application runs, it has sufficient permissions to establish a data connection to your data source. For details, see Access Permissions for Web Applications.

Alternatively, you can use ADO.NET objects to execute SQL commands or stored procedures directly. This allows you to read data straight from the database and send updates back. For details, see Introduction to DataCommand Objects in Visual Studio.

XML Data

Another possible source of data in a Web Forms page is an XML document or stream. You can work with XML data in two ways:

- If the XML data is structured — that is, if it can be represented as relational data (even if it is not stored that way) — then you can convert the XML data into a dataset and use ADO.NET data functions to read and update the data. This allows you to take advantage of the comparatively sophisticated and simple data-processing functionality of datasets. You can then convert the data back to XML to share with other processes. For details, see Synchronizing a DataSet with an XmlDataDocument.
- If the XML data cannot be represented as relational data, you can use XML parsing and processing functions from the System.Xml namespace to manipulate the data. In Web Forms pages, you can do this using the XML Web Server Control. Alternatively, you can work directly with XML documents in code. For details, see Employing XML in the .NET Framework.

> **Note** You need to be sure that when your application runs, it has sufficient permissions to read (and if necessary, write to) XML files. For details, see Access Permissions for Web Applications.

Other Data Sources

Web Forms pages allow you to work with virtually any other type of data as well. The data-binding architecture of Web Forms pages allows you to bind a control to any structure. In practice, this means you can bind to any arrays or collections available in the page, as well as to properties of the page or of other controls.

For ultimate flexibility, you can perform data binding at run time. Each control, as well as the page itself, supports a data-binding event. By writing handlers for this event, you can bind controls on the page to any data you fetch or calculate during page processing.

For details, see Data Binding Single-Value Web Server Controls at Design Time.

Recommendations for Data Access Strategies | Web Data Access Strategy Recommendations | XML Web Server Control | Employing XML in the .NET Framework

Web Data Access Strategy Recommendations

When designing data access in your Web application, you have a variety of choices to make about how you communicate with a data source, whether you store data between round trips of the page, and if you do store data, where. The choices you make can determine how efficiently your application runs and how well it scales. There is no one data access strategy that is suitable for all situations. In fact, each choice has its own advantages and disadvantages, which you will need to understand.

The following sections detail the basic design choices you must make for Web Forms data access. The choices are presented here in a sequence; each choice is based on a choice you made previously.

> **Security Note** Accessing a database from a Web application introduces security issues that you should be aware of. For details, see Access Permissions for Web Applications. For details about accessing SQL Server, see Accessing SQL Server from a Web Application.

Dataset or Direct Access and Data Reader?

A primary choice is whether you want to cache records in a dataset or whether you want to access the database directly and read records using a data reader. For some database operations, such as creating and editing database structures, you cannot use a dataset. For example, if you want to create a new database table from within your application, you cannot do so using a dataset; instead, you would execute a data command. For general data-access scenarios, however, you can often choose between storing records in a disconnected dataset and working directly with the database using data commands.

> **Note** For details about datasets, see Introduction to Datasets. For details about accessing a database directly, see Introduction to DataCommand Objects in Visual Studio.

Each strategy has inherent advantages that apply to any data access scenario (not just Web Forms pages). For example, datasets make it easier to work with related tables and to work with data from disparate sources. Conversely, using a data reader often results in slightly better performance and memory usage, it eliminates the extra step (and memory requirement) of filling a dataset, and it allows you more direct control over the statements or stored procedures you use. For details about the comparative advantages of each of these approaches in general, see Recommendations for Data Access Strategies.

Datasets and Data Commands in Web Forms Pages

When you are working with Web Forms pages, additional factors come into play when deciding whether to use a dataset or a data reader. A significant factor is the page life cycle — Web Forms pages are initialized, processed, and then discarded with each round trip. If you simply want to display data on the page, then creating a dataset, filling it, and then binding controls to it can represent unnecessary overhead, since the dataset will be discarded immediately. In many cases, it is more efficient to use data reader to fetch the data and then to bind controls to it at run time.

> **Tip** No matter how you decide to get data from the data source, you should always attempt to minimize the amount of data you use in a page. The more data a query or stored procedure brings back, the more database and server resources you use.

In general, therefore, you might want to assume that in Web Forms pages it is usually better to use data commands to execute SQL statement or stored procedures, using a data reader to fetch data. For example, to display information in a **DataList** command, you can execute a SQL statement and then bind the control to a data reader. Exceptions to this general rule might be the following:

- **Working with related tables** Datasets allow you to maintain multiple related tables and include support for relations and referential integrity. Working with related records — for example, reading parent and corresponding child records — can be substantially simpler in a dataset than fetching records independently using when executing commands against a database.
- **Exchanging data with other processes** If your Web Forms page is getting its data from another component, such as an XML Web service, you will almost always use a dataset to hold the local copy of the data. Datasets automatically read and write the XML stream used to communicate between components in the .NET Framework.
- **Working with a static set of records** If you need to use the same set of records repeatedly — for example, when users are paging in a grid — it can be efficient to fill those records into a dataset rather than return to the data source with each round trip. This is particularly true if you want to set aside a particular set of records to work with from a database that is changing frequently.

A more general advantage of using a dataset is that it is easier to program than working directly with data commands. However, you must weigh this advantage carefully against other application requirements.

For details about using data commands, see Introduction to DataCommand Objects in Visual Studio.

Save Dataset or Recreate Each Time?

If you do use a dataset, your next choice is whether you want to recreate it with each round trip. You have two options:

- Each time the page is processed, create an instance of the dataset and fill it. When page processing is finished and the page is sent to the browser, the dataset is discarded.
- Create and fill the dataset once (typically, the first time the page runs). Then save the dataset in a way that you can retrieve it with each subsequent round trip.

Creating the dataset each time means that with each round trip — effectively, each time the user clicks a button on your page — you execute a query or stored procedure against the data source. For example, you might have a Web Forms page where the user wants to page through data. If you create the dataset each time, the Web Forms page executes a query against the data source to get the next set of records to display.

> **Tip** Remember to always minimize data transfer. Whenever practical, use selection criteria to reduce the number of records you need on a page.

If you save and restore the dataset, on the other hand, you do not need to go back to the source just to get a few more records. However, saving the dataset has a number of drawbacks. An important one is that the dataset consumes memory between round trips. If the dataset is very large, for example, it can take considerable server memory to store it. If multiple users create large datasets, you can quickly consume available server memory. (An option is to store data in the page; for details, see the next section.)

Another potential drawback is that the dataset can get out of sync with the data source, since you are not refreshing the dataset each time the user clicks a button. If you are working with very volatile data (inventory data, for instance), you might find it better for your application to recreate the dataset with each round trip.

Cache on the Server or on the Client?

If you decide to save a dataset between round trips, you must decide where to keep it. This issue is the standard one of state maintenance in Web Forms pages — where do you store information you want to preserve between round trips? For information about saving values, see Web Forms State Management.

You have two options:

- On the server, save the dataset in Session state, Application state, or using a cache.
- On the client — that is, in the page — save the dataset using view state or by putting the data into your own hidden field. (View state is also implemented using a hidden field.)

Storing the dataset on the server uses server resources. If you store too much data (a large dataset, or many users storing small datasets), it can affect server performance and scalability. Using a cache can partly offset this problem, because the cache manager will discard the dataset if the server needs memory or if cached data expires. But because the dataset is not guaranteed to be in the cache, you must add logic to your page to check that the dataset is available in the cache; if not, you must recreate it and put a copy back in the cache.

Storing data in the page means that you do not need server resources to save the data. However, the data becomes part of the HTML stream of the page. If the dataset is large, it can substantially affect the time it takes for the page to load into the user's browser and to post the page back to the server. For details about saving data in view state, see Saving Web Forms Page Values using View State.

> **Tip** Always try to keep the size of a dataset to a minimum by filling it with only the records you need.

No matter where you decide to store the dataset, you must add logic to your page to save it and restore it at the appropriate time. The following example shows a typical way to store and restore a dataset in Session state. The dataset `dsCustomers1` is an instance of the dataset class `dsCustomers`. Note that the dataset is stored in Session state as type **Object**. When restoring the dataset from Session state, you must cast it from **Object** back to a dataset class.

```
'Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles MyB
ase.Load
   If Page.IsPostBack Then
      dsCustomers1 = CType(Session("myDsCustomers"), dsCustomers)
   Else
      If Session("myDsCustomers") Is Nothing Then
         OleDbDataAdapter1.Fill(dsCustomers1)
         Session("myDsCustomers") = dsCustomers1
```

```
        End If
    End If
End Sub

//C#
private void Page_Load(object sender, System.EventArgs e)
{
   // Put user code to initialize the page here
    if (Page.IsPostBack)
    {
        dsCustomers1 = (dsCustomers) Session["myDsCustomers"];
    }
    else
    {
        if (Session["myDsCustomers"] == null)
        {
            oleDbDataAdapter1.Fill(dsCustomers1);
            Session["myDsCustomers"] = dsCustomers1;
        }
    }
}
```

Data Walkthroughs for Web Forms Pages

The topics in this section demonstrate various data access strategies for Web applications.

In This Section

Walkthrough: Displaying Data in a Web Forms Page
Gives step-by-step details on displaying data in a Web Forms page using a dataset and common controls provided by ASP.NET.

Walkthrough: Creating Read-Only Data Access in a Web Forms Page
Gives step-by-step details on creating optimized data access in a Web Forms page intended for read-only display.

Walkthrough: Updating Data Using a Database Update Query in Web Forms
Gives step-by-step details on updating data using a database query in a Web Forms page.

Walkthrough: Using a DataGrid Web Control to Read and Write Data
Gives step-by-step details on creating a Web Forms page that updates data rather than merely displaying it.

Walkthrough: Creating Paged Data Access Using a Web Forms Page
Illustrates how to create a Web Forms page that lists data one page at a time.

Visual Basic Code Example Topics
Shows quickstart-like code examples that help you perform common tasks in Visual Basic .NET.

Walkthrough: Displaying Data in a Web Forms Page

Web Forms pages provide you with a variety of ways to work with data. This walkthrough illustrates the simplest way.

In the walkthrough, you will display information from the Northwind Categories table in a data grid on the page. You will create a dataset — an in-memory cache of data — into which you will read information from the database. You will then bind a DataGrid Web server control to the dataset in order to display data.

> **Note** Using a dataset is only one option for data access in Web Forms, and it is not the optimal choice in some scenarios. You will use a dataset in this walkthrough for the sake of simplicity. For more information, see Web Data Access Strategy Recommendations.

In order to complete this walkthrough, you will need:

- Access to a server with the Northwind SQL Server sample database. The SQL Server can be located on the same computer as the Web server or on another server. In either case, you must configure access permissions. For details, see Accessing SQL Server from a Web Application.
- Sufficient permissions to be able to create ASP.NET Web application projects on the computer where your Web server is. For details, see Web Application Security at Design Time in Visual Studio.

The walkthrough is split into a number of smaller pieces:

- Creating the Web application project and a Web Forms page.
- Creating and configuring the dataset you will bind the grid to. This includes creating a query that populates the dataset from the database.
- Adding the **DataGrid** control to the form and binding it to data.
- Add code to fill the dataset.

Creating the Project and Form

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

      When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

      > **Tip** If you have trouble creating a Web application project, see Web Access Failed Dialog Box.

Creating and Configuring a Dataset

In this walkthrough, you will add a dataset to the page. The dataset will contain a single table, the Categories table. (A dataset can contain multiple tables, but in this walkthrough it will contain just one table.)

The dataset does not already exist. Instead of adding it manually to the form, you will perform the following set of steps:

- Create a data adapter using a wizard. The adapter contains SQL statements used to read and write database information. The wizard helps you define the SQL statements you need. If necessary, the wizard also creates a connection to the database.
- Generate the dataset schema. In this process, you will have Visual Studio create a new dataset class based on the tables and columns you are accessing. When you generate the dataset class, you will also add an instance of it to the form.

It is important that you follow all the procedures in this section. Otherwise your page will not have the dataset that you will be using in subsequent parts of the walkthrough.

For details on data adapters, see Introduction to Data Adapters. For details about datasets, see Introduction to Datasets.

Configuring a Data Connection and Data Adapter

To begin, you create a data adapter that contains the SQL statement used to populate the dataset later. As part of this process, you define a connection to access a database. You configure the data adapter using a wizard, which makes it easy to create the SQL statements you need for data access.

> **Note** When the wizard is done, you must continue to the next section in order to generate a dataset and complete the data access portion of your form.

To create the data connection and data adapter

1. From the **Data** tab of the Toolbox, drag an **OleDbDataAdapter** object onto the form.

   > **Note** You could also use the **SqlDataAdapter**, which is optimized for working with SQL Server 7.0 or later. In this walkthrough, you use the **OleDbDataAdapter** because it is more generic, providing ADO.NET access to any OLE DB-compatible data source.

   The **Data Adapter Configuration Wizard** starts, which will help you create both the connection and the adapter.

2. In the wizard, do the following:
   a. In the second pane, create or choose a connection pointing to the SQL Server Northwind database.

      > **Note** You need appropriate read/write permissions on the SQL Server you are using. If SQL Server is on the same computer as IIS, it is recommended that you specify Windows integrated security when creating the connection. Otherwise, you can specify a user name and password and save that information with the connection, but doing so can compromise security. For more information, see Accessing SQL Server from a Web Application.

   b. In the third pane, specify that you want to use a SQL statement to access the database.
   c. In the fourth pane, create the following SQL statement:

      ```
      SELECT CategoryID, CategoryName, Description
      FROM Categories
      ```

      For assistance building the SQL statement, click **Query Builder** to launch the **Query Builder** dialog box.

      > **Note** In this walkthrough, you will populate the dataset with all the rows from the categories table. In production applications, you typically optimize data access by creating a query that returns only the columns and rows you need. For an example, see Walkthrough: Displaying Data in a Windows Form Using a Parameterized Query.

   d. Click **Finish**.

      The wizard creates a connection (**OleDbConnection1**) containing information about how to access your database. You will also have a data adapter (**OleDbDataAdapter1**) that contains a query defining what table and columns in the database you want to access.

3. After the wizard is complete, generate the dataset based on the SQL query that you created during this procedure. For details, see the next section.

   > **Note** For more information, click **Help** while running the wizard or see Data Adapter Configuration Wizard. For details about data adapters, see Introduction to Data Adapters.

Creating the Dataset

After you have established the means to connect to the database and specified the information you want (via the SQL command in the data adapter), you can have Visual Studio create a dataset. Visual Studio can generate the dataset automatically based on the query you specified for the data adapter. The dataset is an instance of the **DataSet** class based on a corresponding schema (.xsd file) that describes the class's elements (table, columns, and constraints). For details about the relationship between datasets and schemas, see Introduction to Data Access with ADO.NET.

To generate a dataset

1. From the **Data** menu, choose **Generate DataSet**.

   Tip If you do not see the **Data** menu, click the form; the form must have focus for the menu to appear.

   The **Generate Dataset** dialog box appears.

2. Select the **New** option and name the dataset **dsCategories**.

   In the list under **Choose which table(s) to add to the dataset**, the categories table should be selected.

3. Check **Add this dataset to the designer**, then click **OK**.

   Visual Studio generates a typed dataset class (**dsCategories**) and a schema that defines the dataset. You will see the new schema (**dsCategories.xsd**) in Solution Explorer.

   Tip In Solution Explorer, click the **Show All Files** toolbar button to see the schema file's dependent .vb or .cs file, which contains the code the defines your new dataset class.

   Finally, Visual Studio adds an instance of the new dataset class (**DsCategories1**) to the form.

At this point you have set up everything you need in order to get information out of a database and into a dataset.

Adding a DataGrid to Display Data

In this walkthrough you will use a **DataGrid** Web server control to display information from the Categories table. You could also use a **DataList** or **Repeater** control to achieve the same results. However, the **DataGrid** control is the easiest control to configure (for example, you do not need to create any templates for it), which will allow you to concentrate on the data aspects of the walkthrough.

To add and configure the control

1. From the **Web Forms** tab of the Toolbox, drag a **DataGrid** control onto the page.
2. At the bottom of the Properties window, choose the **AutoFormat** link and select a predefined format for the grid.
3. In the **DataSource** property, select **DsCategories1** as the data source. This binds the grid to the dataset as a whole.
4. In the **DataMember** property, select **Categories**. If a data source contains more than one bindable object, you can use the **DataMember** property to specify which object to bind to.

   Setting these two properties binds the categories data table in the **DsCategories1** dataset to the grid.

Filling the Dataset and Displaying Data in the DataGrid Control

Although the grid is bound to the dataset you created, the dataset itself is not automatically filled in. Instead, you must fill the dataset yourself by calling a data-adapter method. For details about filling datasets, see Introduction to Datasets.

Even after the dataset is filled in, the **DataGrid** control does not automatically display the data. You must explicitly bind the grid to its data source. For more information, see Introduction to Data Binding in Web Forms Pages.

To fill the dataset and display data in the DataGrid control

1. Double-click the page to display the page's class file in the Code Editor.
2. In the **Page_Load** event handler, call the data adapter's **Fill** method, passing it the dataset you want to populate:

   ```
   OleDbDataAdapter1.Fill(DsCategories1)
   ```

3. Call the **DataGrid** control's **DataBind** method to bind the control to the dataset.

   You do not need to refill the dataset and bind the grid with each round trip. Once the **DataGrid** control has been populated with data, its values are preserved in view state each time the page is posted. Therefore, you only need to fill the dataset and bind the grid the first time the page is called. You can test for this using the page's IsPostBack property.

   The complete handler will look like the following:

   ```
   ' Visual Basic
   Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
   MyBase.Load
      'Put user code to initialize the page here
   ```

```
    If Not IsPostBack Then
       OleDbDataAdapter1.Fill(DsCategories1)
       DataGrid1.DataBind()
    End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   // Put user code to initialize the page here
   if ( !IsPostBack)
   {
      oleDbDataAdapter1.Fill(dsCategories1);
      DataGrid1.DataBind();
   }
}
```

Testing

After adding the code, test data access in the Web Forms page.

To test the Web Forms page

1. Save the page.
2. In Solution Explorer, right-click the page and choose **View in Browser**.

   Confirm that a list of categories is displayed in the grid.

Next Steps

- Format the grid by changing its color, font, and so on.
- Display only selected information in the grid. In many instances, you will base the display on information that the user supplies at run time (for example, you might display authors only from a particular city). To do this, you create a parameterized query. For details, see Walkthrough: Displaying Data in a Windows Form Using a Parameterized Query.
- Use a data reader instead of a dataset as the source of data for the grid. In a page such as this one, where the data is read-only, it is often more efficient to get the data directly from the database rather than first creating and filling a dataset. For an example, see Walkthrough: Creating Read-Only Data Access in a Web Forms Page.
- Separate data access from the user interface. In this walkthrough, you have created a form that accesses the data more-or-less directly (via the dataset). A more flexible and maintainable design is to create a data-access component that handles data access. The form (that is, the user interface) could then interact with the component as needed. The same component could be used by multiple forms (and by other components), which eliminates the overhead and redundancy of redesigning data access for every form you create. For details on creating component-based data access, see Walkthrough: Creating a Distributed Application.
- Learn about the security issues associated with Web Forms. For details, see Overview of Web Application Security Threats.

Data Access in Web Forms Pages | Introduction to Datasets

Walkthrough: Creating Read-Only Data Access in a Web Forms Page

In Web applications, it is very common for a page to simply display data — that is, for the data on the page to be read-only. Typical examples include catalog listings, search results, and so on. Users might act on the data by clicking a button to add an item to a shopping cart or clicking a link on the page, but those actions do not directly affect the data on the page.

In this kind of scenario, data access performance can be optimized in a couple of ways. One is that the Web Forms page does not need to create and populate a dataset. If the page is going to simply display the data directly, there is no particular need to cache it in a dataset. Because of this, a second optimization is that the data components of the page can be reduced to a minimum: because you do not need a dataset, you also do not need a data adapter to populate it. In fact, the only data access components you need are a connection and a data command containing a SQL statement or stored procedure that can be executed to fetch the data.

The only remaining piece is a special data component, the data reader, which can fetch records from the result set and pass them to another component. The data reader is specifically designed to be a read-only, forward-only reader, so it is optimized for extremely fast data access. The data reader returns a structure to which you can bind list controls (**Repeater**, **DataList**, **DataGrid** Web server controls).

This walkthrough illustrates how to create a Web Forms page with an ASP.NET **DataGrid** server control on it that uses a data reader to display read-only data. When you are through, you will have a page that looks like the following:

Start Page | WebForm1.aspx | WebForm1.aspx.vb | **Browse - WebForm1**

au_id	au_fname	au_lname	phone
172-32-1176	Johnson	White	408 496-7223
213-46-8915	Margie	Green	415 986-7020
238-95-7766	Cheryl	Carson	415 548-7723
267-41-2394	Anne	Hunter	408 286-2428
274-80-9391	Dean	Straight	415 834-2919
341-22-1782	Jim	Smith	913 843-0462
409-56-7008	Abraham	Bennet	415 658-9932
472-27-2349	Burt	Gringlesby	707 938-6445
486-29-1786	Charlene	Locksley	415 585-4620
648-92-1872	Reginald	Blotchet-Halls	503 745-6402
672-71-3249	Akiko	Yokomoto	415 935-4228

In order to complete this walkthrough, you will need:

- Access to a server with the Pubs SQL Server sample database. The SQL Server can be located on the same computer as the Web server or on another server. In either case, you must configure access permissions. For details, see Accessing SQL Server from a Web Application.
- Sufficient permissions to be able to create ASP.NET Web application projects on the computer where your Web server is. For details, see Web Application Security at Design Time in Visual Studio.

The walkthrough is split into a number of smaller pieces:

- Creating the Web Forms page.
- Adding the necessary data components.
- Adding the **DataGrid** control to display the data and setting a few of its properties.
- Adding the few lines of code needed to fetch the data and display it in the control.

Creating the Project and Form

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you

have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

> **Tip** If you have trouble creating a Web application project, see Web Access Failed Dialog Box.

Adding the Data Components

To create read-only access to the data, you will need a connection to the database you want to read from. You will also need a data command. The data command includes a SQL statement you can execute to fetch the data. (The data command can reference a stored procedure instead, but in this walkthrough you will create a simple SQL SELECT statement.)

Creating and Configuring the Connection

To begin, add a connection that points to the database you want to read from.

To create the data connection

1. From the **Data** tab of the Toolbox, drag an **OleDbConnection** object onto the page.

   > **Note** You could also use the **SqlConnection** object, which is optimized for working with SQL Server 7.0 or later. In this walkthrough, you use the **OleDbConnection** because it is more generic, providing ADO.NET access to any OLE DB-compatible data source.

2. Select the connection and in the Properties window, click the button in the **ConnectionString** property box.

   The list displays any existing connections and the **<New Connection...>** option.

3. Unless you already have a connection to the SQL Server Pubs database, choose **<New Connection...>**.

   The **Data Link Properties** dialog box is displayed.

4. Create a connection pointing to your SQL Server and the Pubs database, and then click **OK**.

   > **Tip** For assistance in creating a connection, press F1 in the **Data Link Properties** dialog box.

   > **Note** You need appropriate read/write permissions on the SQL Server you are using. If SQL Server is on the same computer as IIS, it is recommended that you specify Windows integrated security when creating the connection. Otherwise, you can specify a user name and password and save that information with the connection, but doing so can compromise security. For more information, see Accessing SQL Server from a Web Application.

   The connection information you specified is saved as the connection string for your connection.

That is all that you need to do for the connection. Now you need to add a command with a SQL statement to fetch the data.

To create the data command and SQL statement

1. From the **Data** tab of the Toolbox, drag an **OleDbCommand** object onto the page.

   > **Note** You could also use the **SqlCommand**, which is optimized for working with SQL Server 7.0 or later. In this walkthrough, you use the **OleDbCommand** because it is more generic, providing ADO.NET access to any OLE DB-compatible data source.

2. Select the command and in the Properties window, click the button in the **Connection** property, and select the connection you made earlier. (You will need to open the **Existing** node.)
3. In the **CommandText** property, click the ellipsis button to open the **Query Builder** dialog box.
4. Use the **Query Builder** dialog box to construct the following SQL statement:

```
Select au_id, au_fname, au_lname, phone
From authors
```

   > **Note** In this walkthrough, you will populate the dataset with all the rows from the authors table. In production applications, you typically optimize data access by creating a query that returns only the columns and rows you

need. For an example, see Walkthrough: Displaying Data in a Windows Form Using a Parameterized Query.

5. When you have finished, close the **Query Builder** dialog box.

   The SQL statement is filled into the **CommandText** property.

You have finished adding data components to the page. You can now add a control to display the data.

Adding a Control to Display Data

In this walkthrough you will use an **DataGrid** Web server control to display information from the authors table. You could also use a **DataList** or **Repeater** control to achieve the same results. However, the **DataGrid** control is the easiest control to configure (for example, you do not need to create any templates for it), which will allow you to concentrate on the data aspects of the walkthrough.

To add and configure the control

1. From the **Web Forms** tab of the Toolbox, drag a **DataGrid** control onto the page.
2. At the bottom of the Properties window, choose the **AutoFormat** link and select a predefined format for the grid.

If you have worked with a data-bound **DataGrid** control before, you might expect to set the control's **DataSource** property. In this example, however, you will not set the data source here; instead, you will set it using code to point to the data reader.

You will also note that you are not explicitly setting the grid columns. In this example, data binding is established at run time for the grid, and the grid will dynamically create and display columns based on the data it is bound to.

> **Note** If you are familiar with the **DataGrid** control, you can pre-format columns for the four columns (ID, first name, last name, and phone). Because this is not a required step (the grid will automatically create columns at run time when it is bound), the walkthrough does not guide you through this procedure.

Adding Code to Fetch and Display the Data

To create optimized read-only data access, you will execute the SQL statement you created with the data command. The command returns a data reader that you can then bind to. You can accomplish all of this with a few lines of code.

To add code to fetch data

1. Double-click the Web Forms page to open the Code Editor and find the **Page_Load** event handler.
2. Create code to perform the following functions:
   a. Create an instance variable of type **OleDbDataReader**.
   b. Open the connection.
   c. Call the data command's **ExecuteReader** method, which executes the SQL statement in the data command and returns its result set into the data reader object.
   d. Set the **DataGrid** control's data source to point to the data reader. You could not do this earlier in the Properties window because the data reader did not exist then.
   e. Bind the **DataGrid** control to the data reader.
   f. Close the data reader.
   g. Close the connection. This is an important step; the connection remains open while the data is being fetched from the database. Therefore, when you no longer need the connection, you want to close it and free the resources it uses.

   The following example shows the code required to perform the above steps.

   > **Note** For clarity, the code explicitly creates a variable to hold the data reader.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Ha
ndles MyBase.Load
   If Not IsPostBack Then
      oleDbConnection1.Open()
      Dim Reader As System.Data.OleDb.OleDbDataReader
      Reader = oleDbCommand1.ExecuteReader()
      DataGrid1.DataSource = Reader
      DataGrid1.DataBind()
```

```
        Reader.Close()
        oleDbConnection1.Close()
    End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
    if (!IsPostBack) {
        oleDbConnection1.Open();
        System.Data.OleDb.OleDbDataReader Reader;
        Reader = oleDbCommand1.ExecuteReader();
        DataGrid1.DataSource = Reader;
        DataGrid1.DataBind();
        Reader.Close();
        oleDbConnection1.Close();
    }
}
```

Testing

After adding the code, test data access in the Web Forms page.

To test the Web Forms page

1. Save the page.
2. In Solution Explorer, right-click the page and choose **View in Browser**.

   Confirm that a list of authors is displayed in the grid.

Next Steps

This walkthrough has illustrated the basic steps involved in using a data reader to display read-only data in the page. Some enhancements you could make to the form in this walkthrough include:

- Format columns in the grid to display the information that will be available at run time.
- Format the grid by changing its color, font, and so on.
- Display data in a different control, such as a **DataList** or **Repeater** control. The process is largely the same. One difference, however, is that you need to create templates, drag controls into the templates, and bind the controls. Because the data binding of the container control is done at run time, you have to create custom binding expressions for the controls in the templates. A typical custom binding expression looks like this:

  ```
  DataBinder.Eval(Container, "DataItem.au_lname")
  ```

  The expression would vary only in the last part (`au_lname`) for each control in the template.

  For information about templates, see Web Server Controls Templates.

- Use a parameterized query to fetch data, which is a very common real-world scenario. In that case, you would create a SQL statement that accepts parameters, and then pass those parameters by filling in the **Parameters** collection of a data command before executing it. For details, see Setting and Getting Data Command Parameters.
- Add paging. This is a variation of a parameterized query. You need to maintain in the page some indication of what records you have displayed. When the user navigates to the next page, you need to pass parameter information with the query to get the next page worth of data. For details on creating paged output, see Paging Behavior in DataGrid Web Server Controls.
- Learn about the security issues associated with Web Forms. For details, see Overview of Web Application Security Threats.

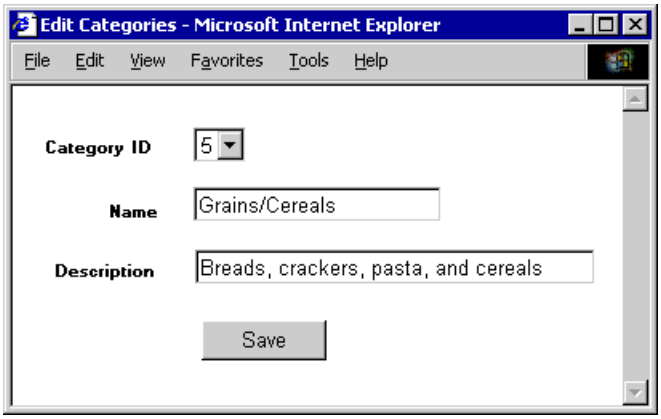
Walkthrough: Updating Data Using a Database Update Query in Web Forms

The Web Forms data-binding architecture allows you to bind control properties to a data source, making it easy to display data on the page. However, the data-binding architecture does not support updates — that is, data binding is one-way in Web Forms pages. Because a majority of Web applications involve reading data and not updating it, one-way data binding keeps the size and complexity of the page architecture to a minimum for the most common scenarios.

However, there are times when you do want to update data. There are several ways to do so. If you are using a dataset, you can write changes to the dataset and then call the data adapter to send changes from the dataset to the database. (For an example of this scenario, see Walkthrough: Using a DataGrid Web Control to Read and Write Data.) Alternatively, you can update the database directly, using SQL statements or stored procedures, which is what this walkthrough illustrates.

> **Note** For details about choosing between these approaches, see Web Data Access Strategy Recommendations.

This walkthrough illustrates how to create a Web Forms page that reads and writes data to a database using SQL statements. For the walkthrough, you will work with the Categories table of the SQL Server Northwind database. In the page, you can select a record, edit it, and then save it to the database. When you are done, your page will look something like the following:



The walkthrough will illustrate a number of concepts:

- Creating command objects that incorporate SQL statements
- Using a SQL statement and a data reader to fetch data from the database
- Creating parameterized queries
- Setting query parameters and executing queries

In order to complete this walkthrough, you will need:

- Access to a server with the Northwind SQL Server sample database. The SQL Server can be located on the same computer as the Web server or on another server. In either case, you must configure access permissions. For details, see Accessing SQL Server from a Web Application.
- Sufficient permissions to be able to create ASP.NET Web application projects on the computer where your Web server is. For details, see Web Application Security at Design Time in Visual Studio.

The walkthrough is split into a number of smaller pieces:

- Creating the Web Forms page.
- Adding the necessary data components.
- Adding controls to display the data.
- Adding code to read and write data.

Creating the Project and Form

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:

a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
b. In the **Templates** pane, choose **ASP.NET Web Application**.
c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

   When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

   Tip If you have trouble creating a Web application project, see Web Access Failed Dialog Box.

Adding the Data Components

To access the data, you will need a connection to the database you want to read from. You will also need several command objects — two to read data from the database using SQL Select statements, and a third to update the database with a SQL Update statement. Two of these commands will require parameters, so that you can pass run-time values to the statements before executing them. (The data commands can reference a stored procedure instead of SQL statements, but in this walkthrough you will use statements.)

Creating and Configuring the Connection

To begin, add a connection that points to the database you want to read from.

To create the data connection

1. From the **Data** tab of the Toolbox, drag a **SqlConnection** object onto the page.

   Note Because you are using SQL Server, you use the **SqlConnection** object, which is optimized for working with SQL Server 7.0 or later. If you are using a different database, you use the **OleDbConnection**, which provides ADO.NET access to any OLE DB-compatible data source.

2. Select the connection and in the Properties window, click the button in the **ConnectionString** property box.

   The list displays any existing connections and the **<New Connection...>** option.

3. Unless you already have a connection to the SQL Server Northwind database, choose **<New Connection...>**.

   The **Data Link Properties** dialog box is displayed.

4. Create a connection pointing to your SQL Server and the Northwind database, and then click **OK**.

   Note You need appropriate read/write permissions on the SQL Server you are using. If SQL Server is on the same computer as IIS, it is recommended that you specify Windows integrated security when creating the connection. Otherwise, you can specify a user name and password and save that information with the connection, but doing so can compromise security. For more information, see Accessing SQL Server from a Web Application.

   The connection information you specified is saved as the connection string for your connection.

Now you need to add commands. You will need three in all, each with a different query:

- One to get all the category ID values.
- One to get a selected category based on an ID that you provide.
- One to update a category with new values.

To create the data command for getting all category ids

1. From the **Data** tab of the Toolbox, drag an **SqlCommand** object onto the page.
2. Rename the command **cmdCategoriesAll**.
3. Select the command and in the Properties window, click the button in the **Connection** property, and select the connection you made earlier. (You will need to open the **Existing** node.)
4. In the **CommandText** property, click the ellipsis button to open the **Query Builder** dialog box.
5. Use the **Query Builder** dialog box to construct the following SQL statement:

```
SELECT CategoryID, CategoryName, Description FROM Categories
```

6. When you have finished, close the **Query Builder** dialog box.

   The SQL statement is filled into the **CommandText** property.

The remaining commands are slightly more complex, in that they require parameters.

To create the data command for getting a single category record

1. Drag a second **SqlCommand** object onto the page and set its **Connection** property to **SqlConnection1**.
2. Name the command **cmdCategoriesById**.
3. In the **CommandText** property, click the ellipsis button to open the **Query Builder** dialog box.
4. Use the **Query Builder** dialog box to construct the following SQL statement:

```
SELECT CategoryID, CategoryName, Description
FROM Categories
WHERE (CategoryID = @categoryid)
```

> **Note** The variable @categoryid is a "named variable." The exact name of the variable you use in the Where clause is not important, but you will need to know it later in the walkthrough. The "@" prefix is required for SQL Server named parameters.

The final command includes an Update statement for sending changes to the database.

To create the data command for updating a category record

1. Drag a third **SqlCommand** object onto the page and set its **Connection** property to **SqlConnection1**.
2. Name the command **cmdCategoriesUpdate**.
3. Set the command's **CommandText** property to the following statement:

```
UPDATE Categories
SET CategoryName = @categoryname, Description = @categorydescription WHERE (CategoryID =
@categoryid)
```

You have finished adding data components to the page.

Adding Controls

In the page, you will need a drop-down list to allow users to select a category ID, some text boxes to display and edit data with, and a button to save changes.

To add controls to the form

1. From the **Web Forms** tab of the Toolbox, add the following controls to the form and set the specified properties as indicated:

Control	Purpose	Properties
DropDownList	Allows user to select a category list that you will provide at run time.	ID: **ddlCategoryID** AutoPostBack: **true**
TextBox	Allows users to edit the category name.	ID: **txtCategoryName**
TextBox	Allows users to edit the category description.	ID: **txtCategoryDescription**
Button	Updates the database with changes.	ID: **btnSave** Text: **Save**

2. Add labels in front of the controls to indicate their function.

> **Tip** If you are working in grid layout mode, you can add literal text using the Flow Layout Panel (HTML Div Controls) from the **HTML** tab of the Toolbox.

Adding Code to Display and Update the Data

To finish the page, you will need to add code to accomplish three tasks:

- When the page is initialized, you need to populate the drop-down list with the category IDs. Since the first category ID will be automatically selected, you can also display the first category name and description in the text boxes.
- When users select a category ID from the drop-down list, you need to determine which ID they selected. You then use that value to execute the SQL statement that brings back a single record.
- When users click the Save button, you need to get their changes and use them to execute an Update statement with the new values.

Populating the Drop-Down List at Page Initialization

To populate the drop-down list, you will execute a query that returns all the records in the Categories table. You only need to do this the first time the page runs; thereafter, the values in the list are preserved in the control's view state.

After executing the query, you will use a data reader (SqlDataReader object) to fetch the records. The data reader is specifically designed to be a read-only, forward-only reader, so it is optimized for extremely fast data access.

To add code to populate the drop-down list

1. Double-click the Web Forms page to open the Code Editor and find the **Page_Load** event handler.
2. Create code to perform the following functions:
   a. Test the page's **IsPostBack** property to determine if this is the first time the page is running. If so, perform the rest of these steps.
   b. Create an instance variable of type **SqlDataReader**.
   c. Open the connection.
   d. Call the **ExecuteReader** method of the **cmdCategoriesAll** object, which executes the SQL statement in the data command and returns its result set to the data reader object.
   e. Provide a way, such as a Boolean flag, to know when you are fetching the first record, because you want to display the information from the record only.
   f. In a loop, use the data reader to fetch each successive record.
   g. For each record, create a new item in the drop-down list and assign the category ID to it.
   h. For the first record only, get the category name and description and set them to the **Text** property of the text boxes.
   i. Close the data reader.
   j. Close the connection. This is an important step; the connection remains open while the data is being fetched from the database. Therefore, when you no longer need the connection, you want to close it and free the resources it uses.

   The following example shows the complete **Page_Load** method with the code required to perform the above steps:

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
MyBase.Load
   If Not IsPostBack Then
      ' Executes only the first time the page is processed. After
      ' that, the list is already in the drop-down list and is
      ' preserved in view state.
      Dim dreader As SqlClient.SqlDataReader
      SqlConnection1.Open()
      dreader = cmdCategoriesAll.ExecuteReader()
      Dim firstrow As Boolean = True
      While dreader.Read()
         ddlCategoryID.Items.Add(New ListItem(dreader(0).ToString()))
         If firstrow Then
            txtCategoryName.Text = dreader(1).ToString()
            txtCategoryDescription.Text = dreader(2).ToString()
            firstrow = False
         End If
      End While
      dreader.Close()
      SqlConnection1.Close()
   End If
```

```
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   if (!IsPostBack)
   {
      // Executes only the first time the page is processed. After
      // that, the list is already in the drop-down list and is
      // preserved in view state.
      System.Data.SqlClient.SqlDataReader dreader;
      sqlConnection1.Open();
      dreader = cmdCategoriesAll.ExecuteReader();
      bool firstrow = true;
      while (dreader.Read())
      {
         ddlCategoryID.Items.Add(new ListItem(dreader[0].ToString()));
         if (firstrow)
         {
            txtCategoryName.Text = dreader[1].ToString();
            txtCategoryDescription.Text = dreader[2].ToString();
            firstrow = false;
         }
      }
      dreader.Close();
      sqlConnection1.Close();
   }
}
```

Displaying a Record When Users Select a Category ID

The drop-down list displays category IDs. When the user selects one — that is, when the control's **SelectedIndexChanged** event is raised — you want to display the corresponding record.

When you created the drop-down list, you set its **AutoPostBack** property to **true**. The result is that the page is posted to the server as soon as the user makes a selection.

To get a category record, you will execute a SQL statement that uses a Where clause to find only the category whose ID the user selected. To pass this value to the statement, you set the value of a parameter (a **SqlParameter** object) that is part of the data command.

To display data for the selected category

1. Double-click the drop-down list to open the Code Editor and create the **SelectedIndexChanged** event handler.
2. Create code to perform the following functions:
   a. Get the text of the user's selection from the drop-down list.
   b. Set the parameter (@categoryid) of the **cmdCategoriesById** command to the selected ID.
   c. Open the connection.
   d. Create a data reader instance variable and call the **ExecuteReader** method of the **cmdCategoriesById** object to execute the command. In this case, you will pass a flag to the method indicating that you want to return only a single record.
   e. Use the data reader to fetch the returned record and then display its values in the text boxes.
   f. Close the data reader.
   g. Close the connection.

   The following example shows the complete **SelectedIndexChanged** method with the code required to perform the above steps:

```
' Visual Basic
Private Sub ddlCategoryID_SelectedIndexChanged(ByVal sender As System.Object, ByVal e As
```

```
System.EventArgs) Handles ddlCategoryID.SelectedIndexChanged
   Dim categoryid As String
   categoryid = ddlCategoryID.SelectedItem.Text
   cmdCategoriesById.Parameters("@categoryid").Value = categoryid
   SqlConnection1.Open()
   Dim dreader As SqlClient.SqlDataReader
   dreader = cmdCategoriesById.ExecuteReader(CommandBehavior.SingleRow)
   If dreader.Read() Then
      txtCategoryName.Text = dreader(1)
      txtCategoryDescription.Text = dreader(2)
   End If
   dreader.Close()
   SqlConnection1.Close()
End Sub

// C#
private void ddlCategoryID_SelectedIndexChanged(object sender, System.EventArgs e)
{
   string categoryid;
   categoryid = ddlCategoryID.SelectedItem.Text;
   cmdCategoriesById.Parameters["@categoryid"].Value = categoryid;
   sqlConnection1.Open();
   System.Data.SqlClient.SqlDataReader dreader;
   dreader = cmdCategoriesById.ExecuteReader(CommandBehavior.SingleRow);
   if (dreader.Read())
   {
      txtCategoryName.Text = dreader[1].ToString();
      txtCategoryDescription.Text = dreader[2].ToString();
   }
   dreader.Close();
   sqlConnection1.Close();
}
```

Updating a Record

Finally, you want to add code that will update the database with changes from the record displayed in the page. As with fetching a single record, the update requires that you set some parameters and then execute a statement (in this case, an Update statement). However, because the Update statement does not return any records, the code for executing the statement is relatively simple.

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

To update records

1. Double-click the Save button to create a **Click** handler.
2. Create code to perform the following functions:
   a. Set parameters (three in all) to the values of the controls in the page.
   b. Open the connection.
   c. Call the **ExecuteNonQuery** method of the **cmdCategoriesUpdate** command.
   d. Close the connection.

The following example shows the complete **Click** method with the code required to perform the above steps:

```
' Visual Basic
Private Sub btnSave_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles btnSave.Click
   With cmdCategoriesUpdate
      .Parameters("@categoryid").Value = ddlCategoryID.SelectedItem.Text
```

```
        .Parameters("@categoryname").Value = txtCategoryName.Text
        .Parameters("@categorydescription").Value = txtCategoryDescription.Text
    End With
    SqlConnection1.Open()
    cmdCategoriesUpdate.ExecuteNonQuery()
    SqlConnection1.Close()
End Sub

// C#
private void btnSave_Click(object sender, System.EventArgs e)
{
    cmdCategoriesUpdate.Parameters["@categoryid"].Value = ddlCategoryID.SelectedItem.Text;
    cmdCategoriesUpdate.Parameters["@categoryname"].Value = txtCategoryName.Text;
    cmdCategoriesUpdate.Parameters["@categorydescription"].Value = txtCategoryDescription.
Text;
    sqlConnection1.Open();
    cmdCategoriesUpdate.ExecuteNonQuery();
    sqlConnection1.Close();
}
```

Testing

You can now test the form to make sure it displays Categories data and that users can make updates.

To test the page

1. In Solution Explorer, right-click the page and choose **View in Browser**.
2. When the page is displayed, make sure that the drop-down list contains a list of category IDs and that the first category is displayed in the text boxes.
3. Select a different category from the list.

   The new record will be displayed.

   > **Note** If selecting a new category ID in the drop-down list does not change the record, make sure that the control's **AutoPostBack** property is set to **true**.

4. Make a change in one of the text boxes, and then click the **Save** button.
5. Move to a different category record, and then back to the one you changed.

   The changes you made are visible when you redisplay the record.

Next Steps

This walkthrough has illustrated the basic steps involved in using a data reader to fetch records directly from the database and using a data command to make updates. To enhance the Web Forms page you have created, you might want to explore some of the following ideas:

- Provide an alternative way for users to select categories. In this walkthrough, the drop-down list displayed category IDs, which ordinarily are not very useful to users. This was done to allow users to edit the name, if desired, and to maintain clarity for how information from database records was moving into and out of controls.

  A relatively easy change would be to display category names as the text of the drop-down list (the information that is visible in the list) and category IDs as the value of the list. (However, this would not allow users to edit the name.) You could then pass the value as a parameter value instead of passing the text.

- Add error checking. Typically, you want to make your code robust by enclosing all data-access statements in try-catch blocks. Data access is subject to many possible problems (many of them out of the control of your application, such as network problems). For details, see Best Practices for Throwing Exceptions from Components.
- Add concurrency control. In this walkthrough, you simply update a record in the database without determining first whether another user might have also made changes. For details, see Concurrency Control in ADO.NET.
- Learn about the security issues associated with Web Forms. For details, see Overview of Web Application Security Threats.

Walkthrough: Using a DataGrid Web Control to Read and Write Data

The architecture of Web Forms data binding makes it easy to display data in page controls. However, data binding is not two-way — that is, data binding reads data from a data source but does not update it. Updating is more complex than displaying data, and because the majority of Web Forms pages do not require that data be written back to the source, Web Forms data binding keeps page sizes and page processing to a minimum by not including update code.

Of course, there are times when you do want to create a Web Forms page that updates data. This walkthrough illustrates one way to do that. It shows how you can use a **DataGrid** control to display data, allow users to edit it, and then send the changed data back to the source.

> **Note** The **DataGrid** control does not inherently include a facility for creating new records. The section "Next Steps" at the end of this topic includes suggestions for adding this ability.

When the page is running, it will look something like the following:

	CategoryID	CategoryName	Description
Edit	1	Beverages	Soft drinks, coffees, teas, beers, and ales
Edit	2	Condiments	Sweet and savory sauces, relishes, spreads, and seasonings
Edit	3	Confections	Desserts, candies, and sweet breads
Edit	4	Dairy Products	Cheeses
Edit	5	Grains/Cereals	Breads, crackers, pasta, and cereal
Edit	6	Meat/Poultry	Prepared meats
Edit	7	Produce	Dried fruit and bean curd
Edit	8	Seafood	Seaweed and fish

In order to complete this walkthrough, you will need:

- Access to a server with the Northwind SQL Server sample database. The SQL Server can be located on the same computer as the Web server or on another server. In either case, you must configure access permissions. For details, see Accessing SQL Server from a Web Application.
- Sufficient permissions to be able to create ASP.NET Web application projects on the computer where your Web server is. For details, see Web Application Security at Design Time in Visual Studio.

The Overall Process

The walkthrough is split into a number of smaller pieces:

- Creating the Web Forms page.
- Adding the necessary data components.
- Adding the **DataGrid** control to display the data.
- Adding code to read data from the database and bind the grid to the data.
- Configuring the **DataGrid** control to allow users to edit data.
- Adding the code to update the data.

Creating the Project and Form

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

> **Tip** If you have trouble creating a Web application project, see Web Access Failed Dialog Box.

Creating and Configuring a Dataset

In Web Forms pages, you have several choices for how you can access data. One is to use a dataset, which is an in-memory data cache. Alternatively, you can access a database directly, using data commands to execute SQL statements or stored procedures. As a general rule, it is easier to update data if you use a dataset, and that is what you will use in this walkthrough. For more information, see Web Data Access Strategy Recommendations.

You do not directly add a dataset to a page. Instead, you will perform the following set of steps:

1. Create a data adapter using a wizard. The adapter contains SQL statements used to read and write database information. The wizard helps you define the SQL statements you need. If necessary, the wizard also creates a connection to the database.
2. Generate the dataset schema. In this process, you will have Visual Studio create a new dataset class based on the tables and columns you are accessing. When you generate the dataset class, you will also add an instance of it to the form.

It is important that you follow all the procedures in this section. Otherwise your page will not have the dataset that you will be using in subsequent parts of the walkthrough.

For an overview of data adapters, see Introduction to Data Adapters. For an overview of datasets, see Introduction to Datasets.

Configuring a Data Connection and Data Adapter

To begin, you create a data adapter that contains the SQL statement used to populate the dataset later. As part of this process, you define a connection to access a database. You configure the data adapter using a wizard, which makes it easy to create the SQL statements you need for data access.

> **Note** When the wizard is done, you must continue to the next section in order to generate a dataset and complete the data access portion of your page.

To create the data connection and data adapter

1. Click WebForm1.aspx, and then from the **Data** tab of the Toolbox, drag a **SqlDataAdapter** object onto the page.

   > **Note** If you are not working with SQL Server, you use an adapter of type **OleDbDataAdapter**, which provides access to any OLE DB-compatible data source.

   The **Data Adapter Configuration Wizard** starts, which will help you create both the connection and the adapter.

2. In the wizard, do the following:
   a. In the second pane, create or choose a connection pointing to the SQL Server Northwind database. For information about getting access to the database, see your database administrator.

      > **Note** You need appropriate read/write permissions on the SQL Server you are using. If SQL Server is on the same computer as IIS, it is recommended that you specify Windows integrated security when creating the connection. Otherwise, you can specify a user name and password and save that information with the connection, but doing so can compromise security. For more information, see Accessing SQL Server from a Web Application.

   b. In the third pane, specify that you want to use a SQL statement to access the database.
   c. In the fourth pane, create the following SQL statement:

      ```
      SELECT CategoryID, CategoryName, Description
      FROM Categories
      ```

      For assistance building the SQL statement, click **Query Builder** to launch the **Query Builder** dialog box.

      > **Note** In this walkthrough, you will populate the dataset with all the rows from the categories table. In production applications, you typically optimize data access by creating a query that returns only the columns and rows you need. For an example, see

Walkthrough: Displaying Data in a Windows Form Using a Parameterized Query.

d. Click **Finish**.

The wizard creates a connection (**SqlConnection1** or **sqlConnection1**) containing information about how to access your database. You will also have a data adapter (**SqlDataAdapter1** or **sqlDataAdapter1**) that contains a query defining what table and columns in the database you want to access.

After the wizard is complete, you need to generate the dataset based on the SQL query that you created during this procedure. For details, see the next section.

Creating the Dataset

After you have established the means to connect to the database and specified the information you want (via the SQL command in the data adapter), you can have Visual Studio create a dataset. Visual Studio can generate the dataset automatically based on the query you specified for the data adapter. The dataset is an instance of the **DataSet** class based on a corresponding schema (.xsd file) that describes the class's elements (table, columns, and constraints). For details about the relationship between datasets and schemas, see Introduction to Data Access with ADO.NET.

To generate a dataset

1. From the **Data** menu, choose **Generate DataSet**.

   Tip If the **Generate DataSet** command is not enabled, click the page; the page must have focus for the command to appear.

   The **Generate Dataset** dialog box appears.

2. Select the **New** option and name the dataset **dsCategories**.

   In the list under **Choose which table(s) to add to the dataset**, make sure the Categories table is selected.

3. Make sure **Add this dataset to the designer** is checked, and then click **OK**.

   Visual Studio generates a typed dataset class (**dsCategories**) and a schema that defines the dataset. You will see the new schema (**dsCategories.xsd**) in Solution Explorer.

   Tip In Solution Explorer, click the **Show All Files** toolbar button to see the schema file's dependent .vb or .cs file, which contains the code that defines your new dataset class.

   Finally, Visual Studio adds an instance of the new dataset class (**dsCategories1**) to the page.

At this point you have set up everything you need in order to get information out of database and into a dataset.

Adding a DataGrid Control to Display the Data

In this walkthrough, you will add a single control — a **DataGrid** control — that can display all the records from the dataset at the same time and allows you to add the ability to edit records.

The data grid must be bound to the dataset in order to display the data.

To add a bound DataGrid control to the form

1. If you have not already done so, switch to the Web Forms Designer by clicking the tab at the top of the current window.
2. From the **Web Forms** tab of the Toolbox, drag a **DataGrid** control onto the form.
3. Select the control, press F4 to display the Properties window, and at the bottom of the window, click **Property Builder**.

   The **DataGrid1 Properties** dialog box appears.

4. In the **General** tab, make the following settings:

Property	Setting	Description
DataSource	dsCategories1	Binds the grid to the dataset.
DataMember	Categories	Specifies that the grid should display data from the categories table in the dataset
Data key field	CategoryID	Specifies that the primary key for categories record is the CategoryID column. This will allow you later to identify which record to update in the dataset.

5. Click **OK** to close the **DataGrid1 Properties** dialog box.
6. If you want to change the appearance of the grid, set the **Font**, **BackColor**, and other properties.

   Tip An easy way to set the grid's appearance is to click **Auto Format** at the bottom of the Properties window and select a predefined look.

Filling the Dataset and Displaying Data in the DataGrid Control

Although the grid is bound to the dataset you created, the dataset itself is not automatically filled in. Instead, you must fill the dataset yourself by calling a data-adapter method. For details about filling datasets, see Introduction to Datasets.

Even after the dataset is filled in, the **DataGrid** control does not automatically display the data. You must explicitly bind the grid to its data source. For more information, see Introduction to Data Binding in Web Forms Pages.

To fill the dataset and display data in the DataGrid control

1. Double-click the page to display the page's class file in the Code Editor.
2. In the **Page_Load** event handler, call the data adapter's **Fill** method, passing it the dataset you want to populate:

```
' Visual Basic
SqlDataAdapter1.Fill(DsCategories1)

//C#
sqlDataAdapter1.Fill(dsCategories1);
```

3. Call the **DataGrid** control's **DataBind** method to bind the control to the dataset. You do not want to rebind the control each time the page makes a round trip, however, because if you do, you will lose changes that the user has made in the grid. You should therefore bind the grid only at these times:

   - The first time the page is called.
   - When the dataset has changed.

   For now, you want to bind the grid the first time the page is called, which you can do by testing the page's **IsPostBack** property. Add code to the **Page_Load** event handler after the call to the adapter's **Fill** method. The complete handler will look like the following:

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
MyBase.Load
   'Put user code to initialize the page here
   SqlDataAdapter1.Fill(DsCategories1)
   If Not IsPostBack Then
      DataGrid1.DataBind()
   End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   // Put user code to initialize the page here
   sqlDataAdapter1.Fill(dsCategories1);
   if (!IsPostBack)
   {
      DataGrid1.DataBind();
   }
}
```

Adding the Ability to Edit Data

As configured, the **DataGrid** control will display information from the Categories table. But you also want users to be able to edit individual rows in the grid. To do this, you add an Edit button to each row of the grid. The user clicks the button and the grid is

redisplayed in edit mode, with text boxes where users can edit the individual columns. When the row is in edit mode, the Edit button is replaced with two other buttons, an Update button and a Cancel button, as shown in the following figure:

	CategoryID	CategoryName	Description
Update Cancel	1	Beverages	Soft drinks, coffees, teas,
Edit	2	Condiments	Sweet and savory sauces, relishes, spreads, and seasonings
Edit	3	Confections	Desserts, candies, and sweet breads
Edit	4	Dairy Products	Cheeses
Edit	5	Grains/Cereals	Breads, crackers, pasta, and cereal
Edit	6	Meat/Poultry	Prepared meats
Edit	7	Produce	Dried fruit and bean curd
Edit	8	Seafood	Seaweed and fish

You can set properties of the **DataGrid** control to display these buttons. However, the buttons are not hooked up automatically; instead, when an Edit or Cancel or Update button is clicked, it raises an event that you respond to. You will need to add short event handlers that do the following:

- Edit button – set the current row into edit mode.
- Cancel button – return the row to display mode.

The event handler for the Update button is more involved, since it performs the update that is the heart of this walkthrough. You will read about this in the next section.

To add editing capability to the DataGrid control

1. In Design view of the Web Forms Designer, select the **DataGrid** control, press F4 to display the Properties window, and then click **Property Builder** at the bottom of the window.

   The **DataGrid1 Properties** dialog box is displayed.

2. Click the **Columns** tab.
3. Under **Column list**, scroll down in the **Available columns** list and open the **Button Column** node.
4. Select **Edit, Update, Cancel** and click the add ( )button to add the buttons to the **Selected columns** box.
5. Click **OK**.

   The **DataGrid** control is redisplayed with an Edit link button in the left-hand column. (You do not initially see the Update and Cancel buttons.)

Now that you have the Edit button, you need to create the event handlers to set edit mode for the rows. To control edit mode, you set the **DataGrid** control's **EditItemIndex** property to the index (zero-based) of the row to edit. For example, to put the third row into edit mode, you set the property to 2. To return a row to display mode, you set the property to –1. After changing edit mode, you must rebind the grid so it displays the data in the row.

You can determine what row the user is in from the event-object passed to the handler. The event object for these events contains an **Item** property that represents the entire **DataGrid** row being updated. The **Item** object in turn supports various properties, including the **Item.ItemIndex** property, which returns the index value of the row you are working with.

To set edit modes

1. (In Visual Basic) Right-click the page and choose **View Code** to open the page's class file in the Code Editor.

   -or-

   (In Visual C#) In Design view, select the grid and then press F4 to open the Properties window.

2. (In Visual Basic) In the left-hand drop-down list at the top of the Code Editor, select **DataGrid1**.

   -or-

   (In Visual C#) Click the Events button ( ) at the top of the Properties window.

3. (In Visual Basic) In the right-hand drop-down list at the top of the Code Editor, select **EditCommand**.

   -or-

   (In Visual C#) Double-click **EditCommand** in the Properties window.

A **DataGrid1_EditCommand** handler is created.

4. Repeat Steps 2 and 3 for the **CancelCommand** event.

   A **DataGrid1_CancelCommand** handler is created.

5. In the **EditCommand** event handler, add the following code:

```
' Visual Basic
DataGrid1.EditItemIndex = e.Item.ItemIndex
DataGrid1.DataBind()

// C#
DataGrid1.EditItemIndex = e.Item.ItemIndex;
DataGrid1.DataBind();
```

6. In the **CancelCommand** event handler, add the following code:

```
' Visual Basic
DataGrid1.EditItemIndex = -1
DataGrid1.DataBind()

// C#
DataGrid1.EditItemIndex = -1;
DataGrid1.DataBind();
```

Testing What You Have So Far

You now have a **DataGrid** control that displays data from a dataset (after the dataset is filled from the database) and you have configured the grid with an Edit button for each row. Even though the page is not yet complete, it is useful to test it now to make sure that the edit capability is working correctly.

To test what you have so far

1. In Solution Explorer, right-click your Web Forms page and choose **View in Browser**.

   The project is compiled and the Web Forms page appears in a browser pane in the designer. If everything is working correctly, the grid will be filled with data and the first column in the grid will contain links that read "Edit."

2. Click the **Edit** link for any row in the grid.

   The row is redisplayed with these changes:

   - The Edit link is replaced with Update and Cancel links.
   - The data is redisplayed in **TextBox** controls.

3. Click **Cancel**.

   The row is redisplayed in its original form.

The next section details how you can have the Update link write changes from the grid to the dataset and database.

Updating the Dataset and Database

Up to this point, the **DataGrid** control has done most of the work involved in simply displaying data. However, as with other ASP.NET server controls, the grid does not include automatic provisions for updates — that is, for taking changes made by a user in the grid and sending them back to the data source. To perform updates, you will need to write some code.

The update will actually occur in two stages. First, you must update the dataset with changes made in the grid. Then you must write changes from the dataset back to the database. For more information, see Introduction to Dataset Updates.

When a grid row is in edit mode, the leftmost column contains an Update link. When users click the link, it raises an **UpdateCommand** event. You will write all your update code in the handler for this event.

To create the UpdateCommand handler

1. (In Visual Basic) If it is not already open, open the Code Editor again.

-or-

(In Visual C#) In Design view, select the grid and then press F4 to open the Properties window.

2. (In Visual Basic) In the left-hand drop-down list at the top of the Code Editor, select DataGrid1.

   -or-

   (In Visual C#) Click the Events button ( ) at the top of the Properties window.

3. (In Visual Basic) In the right-hand drop-down list at the top of the Code Editor, select **UpdateCommand**.

   -or-

   (In Visual C#) Double-click **UpdateCommand** in the grid.

   A **DataGrid1_UpdateCommand** event handler is created.

Steps for Updating From the DataGrid Control

The outline for what you will be doing is this:

1. Determine what row (by index) in the DataGrid control was updated. Then get the datakey out of that grid row so that you identify what row (by ID) is being updated.
2. Get the changed values out of the grid row that the user updated.
3. Use the datakey value to find the corresponding row in the dataset table and then write the changes to that row. At this point, you have updated the dataset, but not yet the database itself.
4. Send changes from the dataset to the database. This executes a SQL command or stored procedure that copies changes from the dataset to the database.
5. Refresh the contents of the **DataGrid** control.
6. The following sections explain the details of each of these steps. If you prefer, you can skip these explanations and go directly to the code that follows.

To update from the DataGrid control

1. Identify what **DataGrid** row was updated by getting the **ItemIndex** property of the row (**Item** object) passed in the event object. Then use the index value to get the corresponding value out of the grid's **DataKeys** collection:

```
' Visual Basic
Dim key As String = DataGrid1.DataKeys(e.Item.ItemIndex).ToString()

// C#
string key = DataGrid1.DataKeys[e.Item.ItemIndex].ToString();
```

2. Get the changed values out of the **DataGrid** row. To do so:
   a. From the item passed in the event object, get the appropriate cell (zero-based) out of the **Cells** collection from the item passed in the event object. For example, the left-most column in the grid is **Cells(0)**.
   b. For each cell, get its **Controls** collection, which contains all the elements that appear in the cell.
   c. Get the first (and only) control out of the collection — in this case, a **TextBox** control. To get the **TextBox**, declare a local variable of type **TextBox** and cast the object in the Controls collection to it.
   d. Get the **TextBox** control's value (its **Text** property).

   The following example shows how to perform these steps.

```
' Visual Basic
Dim categoryName, categoryDescription As String
Dim tb As TextBox
tb = CType(e.Item.Cells(2).Controls(0), TextBox)
categoryName = tb.Text
tb = CType(e.Item.Cells(3).Controls(0), TextBox)
categoryDescription = tb.Text
```

```
// C#
string categoryName;
string categoryDescription;
TextBox tb;
tb = (TextBox) e.Item.Cells[2].Controls[0];
categoryName = tb.Text;
tb = (TextBox) e.Item.Cells[3].Controls[0];
categoryDescription = tb.Text
```

3. Find the corresponding row in the data table. The typed **dsCategories** dataset contains a special **FindBy** method — in this case, the **FindByCategoryID** method — that locates a row by its primary key and returns a reference to it. Create a variable for the typed data row and call the method:

```
' Visual Basic
Dim r As dsCategories.CategoriesRow
r = DsCategories1.Categories.FindByCategoryID(key)

// C#
dsCategories.CategoriesRow r;
r = dsCategories1.Categories.FindByCategoryID(int.Parse(key));
```

4. Update the row by changing values in the row you located in Step 3, as in the following example:

```
' Visual Basic
r.CategoryName = categoryName
r.Description = categoryDescription

// C#
r.CategoryName = categoryName;
r.Description = categoryDescription;
```

5. Send changes from the dataset to the database by calling the data adapter's **Update** method:

```
' Visual Basic
SqlDataAdapter1.Update(DsCategories1)

DataGrid1.DataBind()

// C#
sqlDataAdapter1.Update(dsCategories1);
DataGrid1.DataBind();
```

6. Switch the current row in the grid out of editing mode.

```
' Visual Basic
DataGrid1.EditItemIndex = -1

// C#
DataGrid1.EditItemIndex = -1;
```

7. Data-bind the **DataGrid** control:

```
' Visual Basic
DataGrid1.DataBind()

// C#
DataGrid1.DataBind();
```

The following code shows what the completed **UpdateCommand** event handler looks like. Copy this code and paste it into the

class file for the Web Forms page.

Tip Be sure to overwrite the skeleton event handler you created earlier, otherwise you will have two methods with identical names and signatures.

```
' Visual Basic
Private Sub DataGrid1_UpdateCommand(ByVal source As Object, ByVal e As System.Web.UI.WebContr
ols.DataGridCommandEventArgs) Handles DataGrid1.UpdateCommand
    Dim categoryName, categoryDescription As String

    ' Gets the value of the key field of the row being updated
    Dim key As String = DataGrid1.DataKeys(e.Item.ItemIndex).ToString()

    ' Gets get the value of the controls (textboxes) that the user
    ' updated. The DataGrid columns are exposed as the Cells collection.
    ' Each cell has a collection of controls. In this case, there is only one
    ' control in each cell -- a TextBox control. To get its value,
    ' you copy the TextBox to a local instance (which requires casting)
    ' and extract its Text property.
    '
    ' The first column -- Cells(0) -- contains the Update and Cancel buttons.
    Dim tb As TextBox

    ' Gets the value the TextBox control in the third column
    tb = CType(e.Item.Cells(2).Controls(0), TextBox)
    categoryName = tb.Text

    ' Gets the value the TextBox control in the fourth column
    tb = CType(e.Item.Cells(3).Controls(0), TextBox)
    categoryDescription = tb.Text

    ' Finds the row in the dataset table that matches the
    ' one the user updated in the grid. This example uses a
    ' special Find method defined for the typed dataset, which
    ' returns a reference to the row.
    Dim r As dsCategories.CategoriesRow
    r = DsCategories1.Categories.FindByCategoryID(key)

    ' Updates the dataset table.
    r.CategoryName = categoryName
    r.Description = categoryDescription

    ' Calls a SQL statement to update the database from the dataset
    SqlDataAdapter1.Update(DsCategories1)

    ' Takes the DataGrid row out of editing mode
    DataGrid1.EditItemIndex = -1

    ' Refreshes the grid
    DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_UpdateCommand(object source, System.Web.UI.WebControls.DataGridCommand
EventArgs e)
{
   string categoryName, categoryDescription;

   // Gets the value of the key field of the row being updated
   string key = DataGrid1.DataKeys[e.Item.ItemIndex].ToString();

   // Gets get the value of the controls (textboxes) that the user
   // updated. The DataGrid columns are exposed as the Cells collection.
   // Each cell has a collection of controls. In this case, there is only    one
   // control in each cell -- a TextBox control. To get its value,
   // you copy the TextBox to a local instance (which requires casting)
   // and extract its Text property.
   //
```

```
    // The first column -- Cells(0) -- contains the Update and Cancel buttons.
    TextBox tb;

    // Gets the value the TextBox control in the third column
    tb = (TextBox)(e.Item.Cells[2].Controls[0]);
    categoryName = tb.Text;

    // Gets the value the TextBox control in the fourth column
    tb = (TextBox)(e.Item.Cells[3].Controls[0]);
    categoryDescription = tb.Text;

    // Finds the row in the dataset table that matches the
    // one the user updated in the grid. This example uses a
    // special Find method defined for the typed dataset, which
    // returns a reference to the row.
    dsCategories.CategoriesRow r;
    r = dsCategories1.Categories.FindByCategoryID(int.Parse(key));

    // Updates the dataset table.
    r.CategoryName = categoryName;
    r.Description = categoryDescription;

    // Calls a SQL statement to update the database from the dataset
    sqlDataAdapter1.Update(dsCategories1);

    // Takes the DataGrid row out of editing mode
    DataGrid1.EditItemIndex = -1;

    // Refreshes the grid
    DataGrid1.DataBind();
}
```

Testing

You are now finished. To illustrate how the grid works and make sure it is updating data properly, you should test the page.

To test the page

1. In Solution Explorer, right-click your Web Forms page and choose **View in Browser**.

   The project is compiled and the Web Forms page appears in a browser pane in the designer.

2. Click the **Edit** link for any row in the grid, and edit the row using the text boxes.
3. Click **Update**.

   The grid is redisplayed with your changes. If you examine the database, you will see that the change has been written there are well.

Next Steps

In this walkthrough, you used a **DataGrid** control on a Web Forms page not just to view data, but also to edit it. For the sake of clarity, the walkthrough skipped some details that you would likely want to think about in a production application. Some of the areas in which you might want to enhance what you have learned in this walkthrough are:

Enhancing the DataGrid Control

This walkthrough did not take advantage of some of the DataGrid control's more advanced features. Some of the enhancements you could make are:

- Configure individual columns in the grid by choosing specific columns to display, changing column headers and so on. For details, see Adding Bound Columns to a DataGrid Web Server Control and Specifying Grid Item Format in a DataGrid Web Server Control
- Allow users to delete rows. For details, see Allowing Users to Delete Items in a DataGrid Web Server Control. In addition to specifying a Delete button, you would need to add code to remove records from the dataset. For details, see Deleting Records in a Dataset.
- Use paging. In this instance, you only displayed a few records. However, it is common to display many more, and if so, it is

desirable to allow the grid to display information a page at a time. For details, see Paging Behavior in DataGrid Web Server Controls.

Caching the Dataset

In the walkthrough, the dataset is reinstantiated and refilled from the database each time the page makes a round trip to the server. This strategy, while straightforward to implement, can result in unnecessary traffic to your database server.

An alternative is to store the dataset after it is filled and each time it is changed. Then, instead of rereading the database information, you can restore the dataset with each round trip. There are a variety of options for storing the dataset, including in session state (on the server) or in view state (on the client, in the page). For details about what strategy to use, see State Management Recommendations.

For example, if you want to store the dataset in session state, you might include code such as the following in the **Page_Load** event handler:

```
' Visual Basic
If Session("mydatset") Is Nothing Then
   SqlDataAdapter1.Fill(DsCategories1)
   Session("mydataset") = DsCategories1
Else
   DsCategories1 = CType(Session("mydatset"), dsCategories)
End If
If Not Page.IsPostBack Then
   DataGrid1.DataBind()
End If

// C#
if (Session["mydatset"] == null)
{
   sqlDataAdapter1.Fill(dsCategories1);
   Session["mydataset"] = dsCategories1;
}
else
{
   dsCategories1 = (dsCategories)Session["mydatset"];
}
if (! Page.IsPostBack)
   {
        DataGrid1.DataBind();
   }
```

Note that if you store a dataset in Session or Application state, you need to cast it to the appropriate dataset type when you get it back out.

Be sure to refresh the copy of the dataset in session state each time it changes. For example, you might add the following line in the **UpdateCommand** event handler immediately after you update the database:

```
' Visual Basic
SqlDataAdapter1.Update(DsCategories1)
Session("mydataset") = DsCategories1

// C#
sqlDataAdapter1.Update(dsCategories1);
Session["mydataset"] = dsCategories1;
```

Using Direct Access to the Database instead of a Dataset

In the walkthrough, you created a dataset and bound the grid to it. To update the database, you first updated the dataset, then used the data adapter's **Update** method to send changes to the database.

Using a dataset makes it easy to perform updates, but at the cost of some memory and a very slight performance overhead. As an alternative, you can use data commands (OleDbCommand Class or SqlCommand Class objects) to execute SQL statements or stored procedures directly. For example, you can configure a data command with a parameterized SQL Update statement to update the Categories table in the database. After getting the changes from the grid, you set parameters for the Update statement

and then execute it.

For more information, see Introduction to DataCommand Objects in Visual Studio.

Validating Data

In a production application, you would probably include validation checks to be sure that the changes entered by a user were valid. For details, see Data Validation in Datasets.

Concurrency Control

In the walkthrough, you sent updates to the database without worrying about whether the record you were updating had been changed by another user. However, in production applications, you will usually want to include error checking to be sure that you maintain the integrity of your database. For details, see Concurrency Control in ADO.NET.

Adding Records Using the DataGrid Control

Although the **DataGrid** control allows you to display and edit data, it does not directly include the ability to add new records to a dataset or to a database table. You can add this ability indirectly by using a strategy such as the following:

- Add a new, blank record to the data source.
- Rebind the grid; this will display the new, blank record.
- Put the new grid row into edit mode, and when the user saves changes, update the new record with the user's information, as you would any existing record.

The exact steps you follow depend on the type of data source you are using (for example, whether it is a dataset or the database itself). You might also encounter limitations imposed on new records by primary key or foreign key constraints.

An example of adding a new record using the **DataGrid** control is illustrated in Top Questions about the DataGrid Web Server Control.

Security

When you create Web Forms, you should understand the types of security issues that can arise. For details, see Overview of Web Application Security Threats.

Walkthrough: Creating Paged Data Access Using a Web Forms Page

A common scenario in Web applications is to display a list — for example, a list of search results or of products from a catalog. Unless the list is short, it is typical for the list to be displayed in pages, with a way provided for users to navigate between them. This walkthrough illustrates one way to create paged output using a **DataGrid** Web server control.

There are a number of ways to create paged output, including:

- Create and fill a dataset for each page. This strategy is simple, allowing you to take advantage of the built-in paging features of the **DataGrid** control. However, it is not very efficient, since it gets the entire table from the database each time the user moves to another page. For details, see Specifying Paging Behavior in a DataGrid Web Server Control.
- Create a dataset and cache it. You can create a dataset and then store it (for example, in Session state). This saves the overhead of getting the table from the database each time, but still involves the overhead of storing the entire table in server memory. For small tables, this can be an efficient way to work.
- Fetch a page a worth of data from the database as needed. This method is efficient in two ways: it transfers only the minimum amount of data required each time, and it does not require server memory to store a dataset. However, it is the most complicated to create.

This walkthrough will illustrate the last method. When you are through, you will have a page that looks like the following:

CustomerID	CompanyName	City
ALFKI	Alfreds Futterkiste	Berlin
ANATR	Ana Trujillo Emparedados y helados	México D.F.
ANTON	Antonio Moreno Taquería	México D.F.
AROUT	Around the Horn	London
BERGS	Berglunds snabbköp	Luleå
BLAUS	Blauer See Delikatessen	Mannheim
BLONP	Blondesddsl père et fils	Strasbourg
BOLID	Bólido Comidas preparadas	Madrid
BONAP	Bon app'	Marseille
BOTTM	Bottom-Dollar Markets	Tsawassen

In order to complete this walkthrough, you will need:

- Access to a server with the Northwind SQL Server sample database. The SQL Server can be located on the same computer as the Web server or on another server. In either case, you must configure access permissions. For details, see Accessing SQL Server from a Web Application.
- Sufficient permissions to be able to create ASP.NET Web application projects on the computer where your Web server is. For details, see Web Application Security at Design Time in Visual Studio.

The walkthrough is split into a number of smaller pieces:

- Creating the Web application project and Web Forms page.
- Adding the data components needed to get data from the database.
- Adding the **DataGrid** control to the form.
- Adding code to fetch the right data when users move from page to page.

Because this walkthrough focuses on some more advanced concepts of Web Forms pages, it assumes that you are generally familiar with the following concepts:

- Data commands. For details, see Introduction to DataCommand Objects in Visual Studio.
- Setting command parameters. For details, see Setting and Getting Data Command Parameters.
- Using a data reader as a read-only, forward-only cursor. For details, see Executing a Data Command That Returns a Result Set.
- Saving page information in view state between round trips. For details, see Saving Web Forms Page Values using View State.

Creating the Project and Form

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

   When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

   Tip If you have trouble creating a Web application project, see Web Access Failed Dialog Box.

Adding the Data Components

In this walkthrough, you will need to execute two slightly different SQL statements to get a page of data. Both statements get 10 rows at a time based on a starting ID; they differ only in the WHERE clause.

- The statement for getting the next page of data gets 10 rows out of the table starting with the row after (that is, greater than) the last one on the current page.
- The statement for getting the previous page gets 10 records starting with (that is, equal to) the first one on the previous page.

Note As an alternative to using two statements, you can create a single one and dynamically change the WHERE clause. In this walkthrough, you will use two separate statements to shorten the amount of code you have to write.

In this walkthrough you will be using the Customers table from the SQL Server Northwind database. You can use the techniques illustrated in the walkthrough for any table, subject to the following conditions:

- The table you are accessing has a unique ID.
- The table is ordered by the ID.
- The SQL dialect you are using supports the TOP keyword in a Select statement. The TOP keyword allows you to specify how many rows to return. In this case, of course, you will use the TOP keyword to specify the number of rows per page.

Creating and Configuring the Connection

To begin, add a connection that points to the database you want to read from.

To create the data connection

1. From the **Data** tab of the Toolbox, drag a **SqlConnection** object onto the page.

   Note Because you are using SQL Server, you use the **SqlConnection** object, which is optimized for working with SQL Server 7.0 or later. If you are using a different database, you use the **OleDbConnection** object, which provides ADO.NET access to any OLE DB-compatible data source.

2. Select the connection and in the Properties window, click the button in the **ConnectionString** property box.

   The list displays any existing connections and the **<New Connection...>** option.

3. Unless you already have a connection to the SQL Server Northwind database, choose **<New Connection...>**.

   The **Data Link Properties** dialog box is displayed.

4. Create a connection pointing to your SQL Server and the Northwind database, and then click **OK**.

   Note You need appropriate read/write permissions on the SQL Server you are using. If SQL Server is on the same computer as IIS, it is recommended that you specify Windows integrated security when creating the connection. Otherwise, you can specify a user name and password and save that information with the

connection, but doing so can compromise security. For more information, see Accessing SQL Server from a Web Application.

The connection information you specified is saved as the connection string for your connection.

Now you need to add commands. You will need two in all, one for each SQL statement.

To create the data commands for getting pages of data

1. From the **Data** tab of the Toolbox, drag two **SqlCommand** objects onto the page.
2. Name one of them **cmdNext** and the other **cmdPrevious**.
3. Select the **cmdNext** command and in the Properties window, click the button in the **Connection** property, and select the connection you made earlier. (You will need to open the **Existing** node.)
4. In the **CommandText** property, click the ellipsis button to open the **Query Builder** dialog box.
5. Use the **Query Builder** dialog box to construct the following SQL statement:

```
SELECT TOP 10 CustomerID, CompanyName, City
FROM Customers
WHERE (CustomerID > @customerid)
ORDER BY CustomerID
```

6. When you have finished, close the **Query Builder** dialog box.

   The SQL statement is filled into the **CommandText** property.

7. Repeat Steps 3 through 5 for the `cmdPrevious` ecommand object, creating this query:

```
SELECT TOP 10 CustomerID, CompanyName, City
FROM Customers
WHERE (CustomerID >= @customerid)
ORDER BY CustomerID
```

You have finished adding data components to the page.

Adding the DataGrid Control

To illustrate paging, you will need a **DataGrid** control. For navigation, you will create Previous and Next buttons.

To add and configure DataGrid control

1. From the **Web Forms** tab of the Toolbox, drag a **DataGrid** control onto the page.
2. At the bottom of the Properties window, choose the **AutoFormat** link and select a predefined format for the grid.
3. In the Properties window, click the **Property Builder** link.

   The **DataGrid1 Properties** dialog box appears.

4. Click the **Paging** tab and set the following:

Property	Setting
AllowPaging	Checked
Allow custom paging	Checked
Page size	10
Show navigation buttons	Unchecked

5. Click **OK** to close the dialog box.

> **Note** If you have worked with a data-bound **DataGrid** control before, you might expect to set the control's **DataSource** property. In this example, however, you set the data source in code. Similarly, you will not be setting any columns.

To add navigation buttons

1. From the **Web Forms** tab of the Toolbox, drag two **LinkButton** controls onto the page.
2. Name one of them **btnPrevious** and the other **btnNext**.
3. Set the text of the buttons appropriately. For example, the text of the Next button might be `Next >`.

Adding Code to Fetch and Display a Page of Data

You can now add code to perform paging. The basic logic is that as users navigate, you will execute a SQL statement (using the data command objects you created) and return a data reader (SqlDataReader object) with 10 rows. You bind the **DataGrid** control to the data reader, and the rows are automatically displayed in the grid.

Next Page and Previous Page

The only complication in your page is in implementing navigation, and the issue is this: how do you determine which 10 records to get from the database?

The logic for the Next page is to get 10 rows starting with the row immediately following the last row in the grid. You will therefore get the ID of the last row in the grid and use it as a parameter for the `cmdNext` command you created earlier.

The logic for moving to the previous page is more involved. You want to get 10 rows starting (inclusively) with the first ID of the page preceding the one currently in the grid. For this, you will need to have available the ID of the previous page, and if the user continues paging backward, of the preceding pages as well.

One solution is to create a structure to store the ID of the first record of each page as that page is displayed. That way, when you return to the page, you can get its starting ID and use that as a parameter for the query to fill the page.

Because this is a Web Forms page, you cannot store page information in a variable; you must store it somewhere where it is preserved between round trips. In this walkthrough, you store information in view state, which places it into the page itself (in a hidden field). You will need to store two types of items:

- The current page number. You will use this as an index value, and it will also tell you when the user has navigated back to the first page.
- For each page, the ID of the first row in the grid. You will create a new item in view state for each page. The name of the item is the page number and the value of it is the ID.

For example, if you are on the third page of the grid, you will have added four items to view state, something like these:

```
CurrentPage=3
0=ALFKI
1=BSBEV
2=FAMIA
```

The following sections show you the code that you will need to implement the paging logic.

Displaying Data in the Grid

Filling the grid is the same no matter which way the user has navigated. You can therefore create a generic method that executes either the `cmdNext` or `cmdPrevious` command, depending on which one is passed to the method.

To display data in the grid

1. Create a private variable called `CurrentPage`. You will set the value of this variable in other methods later.
2. Create a method (perhaps named FillGrid) that accepts a data command (SqlCommand) as a parameter.
3. Instantiate a data reader.
4. Open a connection and the data command's ExecuteReader method to execute its SQL statement and fetch rows.
5. Set the **DataGrid** control's **DataSource** property to the data reader and then bind the grid.
6. Close the data reader and the connection.
7. Save two values in view state:

   - The value of the `CurrentPage` variable.
   - The value of the ID column of the first row in the grid. Store the value in a view state item whose name is the page number. The logic looks like this:

     ```
     ' Visual Basic
     ViewState(CurrentPage.ToString()) = DataGrid1.Items(0).Cells(0).Text

     // C#
     ```

```
ViewState[CurrentPage.ToString()] = DataGrid1.Items[0].Cells[0].Text;
```

8. Finally, determine whether you are at the end of the table. For simplicity, in this walkthrough you will simply test whether the query returned fewer rows than the page size (10). If you have reached the end of the table, disable the Next button so that users do not try to continue.

   Note For another suggestion about how to determine whether you are at the end of the table, see "Next Steps" later in this walkthrough.

   The following example shows how you create the `CurrentPage` variable:

```
' Visual Basic
Public Class WebForm1
    Inherits System.Web.UI.Page
    Private CurrentPage As Integer
   ' more declarations here

//C#
public class WebForm1 : System.Web.UI.Page
{
   private int CurrentPage;
   // more declarations here
```

   The following example shows what the code looks like for the complete, generic method:

```
' Visual Basic
Private Sub FillGrid(ByVal currentSqlCommand as SqlClient.SqlCommand)
   Dim dr As SqlClient.SqlDataReader
   SqlConnection1.Open()
   dr = currentSqlCommand.ExecuteReader()
   DataGrid1.DataSource = dr
   DataGrid1.DataBind()
   dr.Close()
   SqlConnection1.Close()
   ViewState("CurrentPage") = CurrentPage
   ViewState(CurrentPage.ToString()) = DataGrid1.Items(0).Cells(0).Text
   ' Determine how many rows were filled into the grid. If it is less
   ' than the number of rows per page, there are no more rows in the
   ' table, and the Next button should be disabled.
   If DataGrid1.Items.Count < DataGrid1.PageSize Then
       btnNext.Enabled = False
   End If
End Sub

//C#
private void FillGrid(System.Data.SqlClient.SqlCommand currentSqlCommand)
{
   System.Data.SqlClient.SqlDataReader dr;
   sqlConnection1.Open();
   dr = currentSqlCommand.ExecuteReader();
   DataGrid1.DataSource = dr;
   DataGrid1.DataBind();
   dr.Close();
   sqlConnection1.Close();
   ViewState["CurrentPage"] = CurrentPage;
   ViewState[CurrentPage.ToString()] = DataGrid1.Items[0].Cells[0].Text;
   // Determine how many rows were filled into the grid. If it is less
   // than the number of rows per page, there are no more rows in the
```

```
    // table, and the Next button should be disabled.
    if (DataGrid1.Items.Count < DataGrid1.PageSize)
    {
       btnNext.Enabled = false;
    }
  }
```

Initializing the Page

The first time the page runs, you want to display the first page of data. Now that you have the generic method for filling the grid, all you need to do is set a parameter and call the method. You want to execute the `cmdNext` command. Set its `@customerid` parameter to an empty string, meaning that the query will bring back the first 10 records greater than "" — that is, the first 10 records in the table. You also want to set the page number (`CurrentPage`) to zero to indicate that you are on the first page.

The code looks like this:

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles MyB
ase.Load
   'Put user code to initialize the page here
   If Not Page.IsPostBack Then
       cmdNext.Parameters("@customerid").Value = ""
       CurrentPage = 0
       FillGrid(cmdNext)
   End If
End Sub

//C#
private void Page_Load(object sender, System.EventArgs e)
{
   // Put user code to initialize the page here
   if (!Page.IsPostBack)
   {
      cmdNext.Parameters["@customerid"].Value = "";
      CurrentPage = 0;
      FillGrid(cmdNext);
   }
}
```

Navigating to the Next Page

When users navigate to the next page, you again want to execute the `cmdNext` command using your generic method. This time, the parameter for the command is the value of the ID column of the last row in the grid.

You also need to increment the page number so that the generic `FillGrid` method can use the number to create another view state item for the ID. To increment the page number, you have to get the old one out of view state. When you do so, you have to cast it to an integer, since all items in view state are stored as objects.

The code for the Next button looks like this:

```
' Visual Basic
Private Sub btnNext_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
btnNext.Click
   ' Get the page number of the page most recently displayed
   CurrentPage = CType(ViewState("CurrentPage"), Integer)
   CurrentPage += 1
   'Gets the id on current page
   Dim lastid As String = DataGrid1.Items(9).Cells(0).Text
   cmdNext.Parameters("@customerid").Value = lastid
   FillGrid(cmdNext)
End Sub

//C#
private void btnNext_Click(object sender, System.EventArgs e)
{
```

```
    // Get the page number of the page most recently displayed
    CurrentPage = (int)(ViewState["CurrentPage"]);
    CurrentPage++;
    // Gets the id on current page
    string lastid = DataGrid1.Items[9].Cells[0].Text;
    cmdNext.Parameters["@customerid"].Value = lastid;
    FillGrid(cmdNext);
}
```

Navigating to the Previous Page

Finally, you need to add code to move backwards. This is where you will use the information you have been storing in view state. First, you get the current page number and then decrement it. Then you look in view state, using the page number as the name, to get the ID of the first row on the page. You use that ID as the parameter for the `cmdPrevious` command, which you pass to the generic `FillGrid` method.

To prevent running off the beginning of the table, you should check that you page count is not below zero. In addition, you should enable the Next button, just in case it was disabled in previous navigation.

```
' Visual Basic
Private Sub btnPrevious_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles btnPrevious.Click
   btnNext.Enabled = True
   CurrentPage = CType(ViewState("CurrentPage"), Integer)
   CurrentPage -= 1
   If CurrentPage >= 0 Then
       Dim firstid As String
       firstid = CType(ViewState(CurrentPage.ToString()), String)
       cmdPrevious.Parameters("@customerid").Value = firstid
       FillGrid(cmdPrevious)
   End If
End Sub

//C#
private void btnPrevious_Click(object sender, System.EventArgs e)
{
   btnNext.Enabled = true;
   CurrentPage = (int)(ViewState["CurrentPage"]);
   CurrentPage--;
   if (CurrentPage >= 0)
   {
      string firstid;
      firstid = (string)(ViewState[CurrentPage.ToString()]);
      cmdPrevious.Parameters["@customerid"].Value = firstid;
      FillGrid(cmdPrevious);
   }
}
```

Testing

After adding the code, test data access in the Web Forms page.

To test the Web Forms page

1. Save the page.
2. In Solution Explorer, right-click the page and choose **View in Browser**.

   Confirm that a list of 10 customers is displayed in the grid.

3. Click the Next and Previous buttons several times to be sure you are navigating correctly. Special tests to make are:

   - On the first page, click Previous; nothing should happen.
   - Click Next till you reach the end of the table and make sure that the Next button is disabled.

Next Steps

This walkthrough has illustrated one method of implementing paging. The scenario illustrated here was simple but complete. In real applications, many additional factors can come into play, and paging can become quite complex. Some issues to think about include:

- To determine when you have reached the end of the file, the walkthrough uses an algorithm that is easy but not perfectly reliable. (It compares the number of returned rows against the number of rows in a page). In a real application, you would want to add a more sophisticated algorithm. One possibility is to do the following:

  1. Add another command object to the page that includes this SQL statement:

     ```
     Select Count(CustomerID) From Customers
     ```

  2. The first time the page runs, execute the command using the command's **ExecuteScalar** method to get the total number of rows in the table. Then calculate the total page count required for the table and store it in both a global variable and in view state. On subsequent posts, get the value back out of view state.
  3. In the `FillGrid` method, check whether the current page has reached the total page count. If so, disable the Next button.

- The walkthrough assumes that the data is not volatile. If other users are adding rows to the table, page boundaries change, and storing the first ID of a given page is not a viable solution.
- You can create a stored procedure to perform the work done here with SQL statements.
- Security. For details, see Overview of Web Application Security Threats.

Web Forms Data Binding

As in most types of forms, Web Forms pages allow you to display information by binding controls to a source of data. However, due to the nature of Web Forms pages themselves and to the architecture of Web programming, data binding in Web Forms pages is somewhat different than it is in other, more traditional forms such as Windows Forms.

The topics in this section discuss how data binding works in Web Forms pages and how to specify data binding for various types of controls.

In This Section

Introduction to Data Binding in Web Forms Pages
Provides an overview of how controls in a Web Forms page are bound to data.
Multi-Record and Single-Value Data Binding for Web Forms Pages
Describes the differences between binding a multi-record control (such as a **DataList** control) and a control that displays only a single data value (such as a **TextBox** control).
Data-Binding Expressions for Web Forms Pages
Describes how Web Forms control data binding is specified through the use of a special syntax.
Data Binding Multi-Record Web Server Controls
Provides step-by-step instructions on how to bind a control such as a **DataList** or **DataGrid** control to a data source containing more than one record.
Data Binding Single-Value Web Server Controls at Design Time
Provides step-by-step instructions on how to bind a Web server control property (using a data-binding expression) to a single data value.
Data Binding HTML Server Controls
Provides step-by-step instructions on how to bind property values of HTML server controls (such as the **HtmlInputText** or **HtmlSelect** control) to a data source.
Data Binding Single-Value Web Server Controls at Run Time
Describes how to programmatically use event handlers to load data values into control properties.

Introduction to Data Binding in Web Forms Pages

As in most types of forms, Web Forms pages allow you to display information by binding controls to a source of data. However, due to the nature of Web Forms pages themselves and to the architecture of Web programming, data binding in Web Forms pages is somewhat different than it is in other, more traditional forms such as Windows Forms.

This topic provides background information on data binding in Web Forms pages, how you work with data binding in your Web applications, and where you can find more information about data binding and data access in Web Forms pages.

Web Forms Data Binding: Read-Only

The data-binding architecture of Web Forms pages is based on the idea that the majority of data access in a Web application is read-only — that is, that pages frequently display information from a data store, but much less frequently need to write data back to the store. There are many examples of pages that present read-only data:

- A search results page for other Web pages, products, and so on. Information in a search results page is often presented as links to other pages, and rarely is there a need for users to enter data to be saved in a database.
- A page that provide sports scores, weather information, and so on.
- A portal page. Many portal pages (such as the MSN home page) allow users to customize the page by choosing from various types of information to display — news, financial information, entertainment options, and so on. The information itself is often provided to the page as XML data that can be transformed according to user preferences.
- A page that provides account and financial transaction information to a bank or brokerage customer.

Because the Web Forms data-binding architecture does not perform updates — that is, it does not write data from the control back to the data source — you must provide this logic. The logic for performing updates in Web Forms pages varies considerably according to a variety of factors:

- What the data source is.
- Whether you are caching data by using a dataset.
- What type of control you are working with — for example, whether the control displays multiple records, as in a grid, or single values, as in a text box.
- What type of concurrency control you want to use.

Because of the variables associated with updating from Web Forms pages, you implement your own update logic to match the specific requirements of your Web Forms page and application. For more information, see Dataset Updates in Visual Studio .NET.

Binding Properties

Data binding in Web Forms pages is flexible — you can bind any property of a control to data. In contrast, in traditional data binding, you typically bind the display property (for example, the text property of a text box) to the data source.

In Web Forms pages, your data source can be almost any type of information available to the page — whether it comes from a database, from an XML document, from another control or process, or even from a calculation you perform yourself.

Web Forms data binding, moreover, allows you to assign this data to any property of any control. Because of this, you can use data binding to perform actions such as:

- Setting the text to display in a **TextBox**, **Label**, **Button**, **LinkButton**, or other control.
- Setting the target page (the HREF attribute) of a link control.
- Binding a **CheckBox** control to a Boolean value to directly set the checked state of the control.
- Setting the graphic of an **Image** control by binding its **ImageUrl** property to a database column containing the URL or name of a graphics file.
- Setting the color, font, or size of controls. This can be useful as a way of implementing user preferences that you store in a database or other data store.

In other words, data binding becomes an automatic way of setting any run-time accessible property of any control on the page.

Binding Multi-Record and Single-Value Controls

There are two types of data binding that a control might support:

- Multi-record controls can display one or more data records at once, such as the **Repeater**, **DataList**, **DataGrid** Web server controls and the **HtmlSelect** HTML server control.

- Single-value controls can display one data value at a time. This includes most Web server and HTML server controls, including the **TextBox**, **Label**, **HtmlInputText**, and **HtmlAnchor** controls.

> **Note** All controls allow you to bind individual properties to single data values. For example, a **DataList** control can display multiple records at once, but you might bind its **BackColor** property to a single data value.

Data binding works differently depending on whether you are binding to multiple records or to a single data value. To display multiple records, you bind a multi-record control to a data source that contains multiple records — an array, a collection, a data table, and so on. The only requirement is that the data source implement the IEnumerable interface. The default behavior is that when data binding occurs, the multi-record control loops through every data item in the data source.

To bind to a single value, on the other hand, you specify what property to bind and what data value it should get its value from.

For more information about how data binding works in each of these types of controls, see Multi-Record and Single-Value Data Binding for Web Forms Pages.

Binding at Design Time vs. at Run Time

If you are binding controls to data in a dataset, you can specify data-binding properties for controls at design time. This includes binding to dataset tables and to data views. For example, you can use design-time tools to specify that a **DataGrid** control be bound to a table in a dataset. For more information, see Data Binding Multi-Record Web Server Controls.

Similarly, you can bind a **TextBox** control to a value in a row returned by a data view. Visual Studio includes tools to help you easily specify this kind of design-time binding. For details, see Data Binding Single-Value Web Server Controls at Design Time.

In some situations, however, it is impractical to specify binding properties at design time. Generally, if the data source you want to bind to does not have an instance on your Web Forms page at design time, you need to perform data binding at run time. Some examples where you might do this include:

- Binding controls to data returned by executing a SQL statement or a stored procedure in a database
- Binding to objects of any sort that are not instantiated until run time.

At run time, controls raise a DataBinding event that you can use to fetch data values and assign them to control properties.

Multi-Record and Single-Value Data Binding for Web Forms Pages

Some Web Forms controls display values from multiple records at once. These controls include the **Repeater**, **DataList**, **DataGrid**, **ListBox**, **CheckBoxList**, and **RadioButtonList** Web server controls, as well as the **HtmlSelect** control. Other controls, such as **Label**, **TextBox**, **CheckBox**, and **Hyperlink** controls, display single values, which in data-binding terms means values from a single record.

Data Binding in Multi-Record Controls

To bind multi-record controls, including the **Repeater**, **DataList**, **DataGrid**, **ListBox**, **RadioButtonList**, **CheckBoxList**, and **HtmlSelect** controls, you set properties that specify where the records are that you want to display. You generally set properties indicating:

- The data source, or the container, containing the records you want to display. A typical data source is a dataset.
- The data member, such as the name of a specific table, if there is more than one bindable member.
- A specific field or column to display. This applies to controls such as the **ListBox** and **HtmlSelect** controls that display multiple data items but only one value from each item.

> **Note** You can bind individual properties of multi-record controls to single data values. For example, a **DataList** control can display multiple records at once, but you might bind its **BackColor** property to a single data value.

Although you often bind to data in a dataset, you can bind a multi-record control to almost any structure that supports the IEnumerable interface. This includes the following:

- ArrayList objects
- Collections
- Data readers (objects of type OleDbDataReader and SqlDataReader)
- DataView objects
- DataRow objects
- DataTable objects in datasets

During data binding, the multi-record control loops through the data source, extracting each item in turn. What happens with each data item in turn depends on what type of multi-record control you are working with. A **DataGrid** control can automatically display all items or a subset of the information based on properties you specify. The **Repeater** and **DataList** controls, in contrast, act as containers for controls embedded in their templates (for information see Web Server Controls Templates), which perform their own data binding.

Design-time and Run-time Data Binding

If there is an instance of the data source on your Web Forms page at design time, you can specify binding at design time also. For example, imagine that you want to bind a **DataGrid** control to a table in a dataset. If there is an instance of the dataset on your Web Forms page, Visual Studio recognizes it as a valid data source and allows you to set the grid's properties to bind to the table. You can bind this way to dataset tables, data views, and other objects on the page.

In many cases, however, the object you want to bind to does not exist until run time. This is true of structures such as an **ArrayList** or similar object, which you typically instantiate and fill at run time. It is also true for some sources that contain data from a database. For instance, you can get data for the page by using a data command to execute a SQL statement, and then fetch the individual data rows using a data reader. Because you cannot put an instance of the data reader directly onto your page, you must bind to it programmatically at run time.

For more information, see Data Binding Multi-Record Web Server Controls.

Binding to Single Data Values

You can bind individual control properties to virtually any information that can be resolved into a single value appropriate for the property you are binding. A very common scenario, for example, is to bind the **Text** property of a **TextBox** control to a data value.

To perform this type of binding, you do not use explicit data binding properties. Instead, you get the data value you want and assign it as a property value of the control.

> **Note** Controls that do not display multiple records — that is, controls other than **DataList**, **DataGrid**, and so on —

do not include explicit data-binding properties.

Design-time Data Binding

At design time, you can bind a control property to a data value using a "data-binding expression." The expression can reference a row in a dataset table or in a data view, or it can reference a property of another control, or almost anything else. You set a property value to this data-binding expression. When the page runs, the data-binding expression is resolved and the resulting value is assigned to the property. For more information, see Data-Binding Expressions for Web Forms Pages.

If you are using a data-binding expression to bind to data in a dataset, creating a reference to one particular record can be impractical. The dataset does not maintain a pointer or support the concept of a "current record," so there is no implicit way to indicate what record to bind to.

> **Note** This is different from Windows Forms. In Windows Forms, the data-binding architecture built into the form maintains its own set of pointers to records in a dataset, so that controls can be bound to a kind of "current record."

There are several ways to pinpoint the record you want to work with when binding to single data values:

- Create a data view that filters a dataset table to return only one record (for example, by filtering on a unique key). You can then bind the controls to the data view. The data-binding expression for this scenario might look something like the following:

  ```
  DataBinder.Eval(DataView1, "[0].au_lname")
  ```

  The index value zero (`[0]`) indicates that the expression will get data from the first w(and presumably, only) record represented by the data view. For details, see Filtering and Sorting Data Using Data Views.

- Fill a dataset with just one record. However, this might not be an efficient way to use datasets.

Alternatively, you can data bind the control at run time. Doing so allows you to determine programmatically what data row to bind to, which can include executing a SQL statement or stored procedure and binding to the results. For details, see Data Binding Single-Value Web Server Controls at Run Time.

Binding Single-value Controls in Templates

Multi-record controls such as the **DataList**, **Repeater**, and the **DataGrid** controls include templates used to render individual records from the data source. The templates in turn often contain single-value controls such as **TextBox** and **Label** controls that are bound to data.

> **Note** For details about templates, see Web Server Controls Templates.

Because the single-value controls in the template can bind to only one value, you need to specify which record to bind to. The parent control makes this possible by exposing two objects that you can use in a data-binding expression:

- The **Container** object refers to the parent control, which in turn is bound to a data source.
- The **DataItem** object references the record currently being processed by the parent control.

A data-binding expression for a **TextBox** control in a **DataList** control template might look like the following:

```
DataBinder.Eval(Container, "DataItem.au_lname")
```

For more information, see Data Binding Single-Value Web Server Controls at Design Time.

Data-Binding Expressions for Web Forms Pages

Data binding individual control properties in Web Forms pages is not implemented by directly tying the property to a source of data. Instead, data binding is implemented by using a special expression format. Information about what data you want to bind to is built into the expression; you then assign the results of the expression to a control property.

For example, imagine that you want to bind a **TextBox** Web server control to some data. You create a data-binding expression and assign it to the control's **Text** property so that the value will be displayed in the control.

The following example shows what the control declaration might look like in HTML view. The control's **Text** property is bound to a data view that contains a single record. The data-binding expression is delimited with the characters `<%#` and `%>`.

```
<asp:TextBox id="TextBox1" runat="server"
   Text='<%# DataView1(0)("au_lname") %>'>
</asp:TextBox>
```

Similarly, you can use a data-binding expression to set the ImageUrl property of an **Image** Web server control. In that case, you are extracting a string from the database that contains the path and filename of the graphic to display. An example might look like the following:

```
<asp:Image id=Image1 runat="server"
   ImageUrl='<%# DataView(0)("productPhotoURL") %>'>
```

In Visual Studio, the Properties window provides you with a tool to create data-binding expressions. Alternatively, you can create them yourself and enter them in HTML view of the Web Forms designer.

Advantages of Using Data-binding Expressions

Using an expression for data binding gives you flexibility in a number of ways:

- You can use any expression, as long as it resolves to a value or values the control can use. Most frequently, the data-binding expression will resolve to a value derived from a data source, but it can also reference properties of the page or of other controls, values that you calculate at run time, or almost anything else.
- You can assign the expression to any property — that is, you can bind any property to data. For example, you can keep information about user preferences in a database and use data binding to implement those preferences in properties for fonts, colors, sizes, styles, and so on. In addition, you can bind more than one control property, which allows you to bind one property to one data source, and another property to a different source.

Using the DataBinder Class for Binding

Although you can data bind using virtually any expression that resolves to a value, in most cases you will bind to a data source of some sort. This is most often a table in a dataset or a data view that contains the single record you are interested in. To simplify this type of data binding, ASP.NET server controls support a class called DataBinder that performs some of the work of extracting data and making it available to a control property.

You use the **DataBinder** class by invoking its **Eval** method, which requires two parameters:

- A reference to the data container, typically the dataset, data table, or data view.
- A reference to the individual value to be derived. This frequently references a single row (row zero) and a column value in that row.

The following example shows the same data binding that was done above for a text box, but this time using the **DataBinder** class.

```
<asp:TextBox id="TextBox1" runat="server"
   Text='<%# DataBinder.Eval(DataView1, "[0].au_lname") %>'>
</asp:TextBox>
```

The earlier example of setting the **ImageUrl** property of an **Image** control might look like the following. In this example, a formatting expression is passed in the optional second parameter of the **DataBinder.Eval** method; the expression adds a path onto the data as a prefix.

```
<asp:Image id=Image1 runat="server"
   ImageUrl='<%# DataBinder.Eval(Container, "DataItem.ProductImage", "http://myserver/myapps/
images/{0}") %>'>
```

The advantages of using the **DataBinder** class are:

- The syntax is consistent for all binding, enforced by the parameters required for the **Eval** method.
- The **DataBinder** class is supported by the Visual Studio design tools for Web Forms pages.
- The class performs type conversion automatically. For example, if you are binding a text box to a data column containing an integer, the **DataBinder** class will convert the integer to a string automatically.
- You can optionally specify a formatting expression that can convert or amend the data.

Resolving Data-binding Expressions

Data-binding expressions must be resolved at run time in order to provide values that controls can bind to. You explicitly perform this step during page processing by calling the DataBind method, which is a method of the System.Web.UI.Control class. You can call the method for individual controls or, more efficiently, you can call it for the **Page** class (which also derives from the **Control** class). The method cascades the call to all child controls, so by calling it once for the page, you invoke it for all controls on the page.

You typically call the **DataBind** method under these circumstances:

- The first time the page runs, but after the data source has been populated (for example, after you have filled a dataset).
- After the data source has changed (for example, because you have updated records in it).

The following example shows a typical way to call the **DataBind** method during the page initialization event:

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles MyB
ase.Load
   SqlDataAdapter1.Fill(DsAuthors1, "authors")
   If Not (Me.IsPostBack) Then
     Me.DataBind()
   End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   SqlDataAdapter1.Fill(dsAuthors1, "authors");
   if (!this.IsPostBack)
   {
      this.DataBind();
   }
}
```

You generally do not want to call the **DataBind** method on each round trip (that is, in the page initialization without checking for a post back), because doing so replaces the values in controls. For example, if you are working with a **DataGrid** control, the control might contain changes that you want to process. When you call **DataBind**, the contents of the grid are replaced with values from the data source. If you do this during page initialization, you will lose the changes in the grid before you get a chance to process them. Instead, you usually call the **DataBind** method in an event handler, after you have performed the data processing for that event.

Data Binding Single-Value Web Server Controls at Design Time | Data Binding HTML Server Controls

Data Binding Multi-Record Web Server Controls

Multi-record controls — such as the **Repeater**, **DataList**, **DataGrid**, **ListBox**, **CheckBoxList**, and **RadioButtonList** controls — are bound to a data source that contains multiple data items. For example, you can bind a **DataGrid** control to a table in a dataset and the control can directly display the data. Or you can bind a **DataList** or **Repeater** control to a table in a dataset and the control can make it available to child controls.

You can also bind an HtmlSelect control to multiple records. The procedure is different than it is for the Web server controls listed above. For details, see Data Binding HTML Server Controls.

> **Note** This procedure discusses setting properties that bind the control to an object containing multiple data items. You can also use data binding to set the value of single-value properties in these controls. For example, you can set the control's **Width** or **BackColor** property using single-value data binding. For details, see Data Binding Single-Value Web Server Controls at Design Time.

To bind a multi-record control

1. Set the control's DataSource property to the object containing the data items you want to bind to.

   The container object must implement the IEnumerable interface; this includes objects such as:

   - ArrayList objects
   - Collections
   - Data readers (objects of type OleDbDataReader and SqlDataReader)
   - DataView objects
   - DataRow objects
   - DataTable objects in datasets

2. If the data source is a dataset, set the DataMember property to the name of the table to bind to. (If this property is not set, by default the first table in the dataset is used.)
3. If you are working with a **DataList** or **DataGrid** control, set the **DataKeyField** property to the name of a column that you can use at run time to identify individual items. If it is available, you usually use the primary key column from the data source.
4. If you are working with a **ListBox**, **DropDownList**, **CheckBoxList**, **RadioButtonList**, or **HtmlSelect** control, set the DataTextField property to the name of the data column to display in the control.
5. Optionally, set the DataValueField property to specify the name of a column that the control should return as its value when the user selects an item.
6. Add code to the Web Forms page to call the control's or the page's DataBind method.

   > **Note** You generally do not want to call the **DataBind** method on each round trip (that is, in the page initialization without checking for a post back), because doing so replaces the values in controls.

   The following example shows how you can data bind a **ListBox** control. The example assumes that you have a dataset called `DsTitles1` that contains a table called `titles`. The table contains two columns, the title column that you assign to the **ListBox** display text and the `title_id` column that you assign as the control's value.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
MyBase.Load
   SqlDataAdapter1.Fill(DsTitles1)
   If Not (Me.IsPostBack) Then
      ListBox1.DataSource = DsTitles1
      ListBox1.DataMember = "titles"
      ListBox1.DataTextField = "title"
      ListBox1.DataValueField = "title_id"
      ListBox1.DataBind()
   End If
End Sub

// C#
```

```
private void Page_Load(object sender, System.EventArgs e)
{
   sqlDataAdapter1.Fill(dsTitles1);
   if (! this.IsPostBack)
   {
      ListBox1.DataSource = dsTitles1;
      ListBox1.DataMember = "titles";
      ListBox1.DataTextField = "title";
      ListBox1.DataValueField = "title_id";
      ListBox1.DataBind();
   }
}
```

The following example shows how to bind a **ListBox** control to the data returned when you use a **DataCommand** object to execute a SQL statement. The command object's **ExecuteReader** method returns a data reader object (in this case, of type SqlDataReader), which you can directly bind a **ListBox** control to.

> **Note** For details about using data commands and data readers, see Executing a Data Command That Returns a Result Set.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
MyBase.Load
   If Not (Me.IsPostBack) Then
      SqlConnection1.Open()
      SqlCommand1.CommandText = "Select au_id, au_lname from authors"
      ListBox1.DataSource = SqlCommand1.ExecuteReader()
      ListBox1.DataTextField = "au_lname"
      ListBox1.DataValueField = "au_id"
      ListBox1.DataBind()
      SqlConnection1.Close()
   End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   if (! this.IsPostBack)
   {
      sqlConnection1.Open();
      sqlCommand1.CommandText = "Select au_id, au_lname from authors";
      ListBox1.DataSource = sqlCommand1.ExecuteReader();
      ListBox1.DataTextField = "au_lname";
      ListBox1.DataValueField = "au_id";
      ListBox1.DataBind();
      sqlConnection1.Close();
   }
}
```

Introduction to Data Access in Web Forms Pages | Multi-Record and Single-Value Data Binding for Web Forms Pages | Data Binding Single-Value Web Server Controls at Design Time

Data Binding Single-Value Web Server Controls at Design Time

You can bind any single-value Web server control property — for example, the **Text** property of a **TextBox** or the **ImageUrl** property of an **Image** control — to a data value. This includes not only display properties, but also behavior properties such as size, width, and font.

> **Note** If you are working with list controls (**Repeater**, **DataList**, **DataGrid**, **CheckBoxList**, and **RadioButtonList**), you specify data binding for the control as a whole using special data-binding properties. For details, see Data Binding Multi-Record Web Server Controls. However, you can bind their single-value properties such as size and font using the procedure in this topic.

You specify single-value data binding by creating a data-binding expression. In Visual Studio, you can use design-time tools to create this expression automatically. When the control performs data binding, it resolves the expression and assigns the resulting value to the specified property. You can data bind as many properties on a control as you need.

> **Note** If you are working with HTML server controls (such as the **HtmlInputText** or **HtmlSelect** control), data-binding procedures are different. For details, see Data Binding HTML Server Controls.

To data bind single-value Web server controls in Design view

1. Select the control, and in the Properties window, click the button in the **(Data Bindings)** property.

   The **DataBindings** dialog box is displayed, showing all the control's properties and data sources available at design time.

2. Under **Bindable Properties**, select the property you want to bind to data.
3. If you want to bind to a data source and member available at design time, select **Simple Binding**. Expand the appropriate node as follows:

   - If you are binding directly to data in a dataset, expand the name of the dataset and then the name of the table. This displays the **DefaultView** object (a data view automatically generated by the dataset), which in turn will expand into **DefaultView.[0]** — that is, to the first record in the data view.

     > **Note** To use this binding effectively, you must set the default data view's RowFilter property at run time so that the data view contains only one record. For details, see Adding Data Views to a Form or Component.

   - If you are adding controls to a template in a **Repeater**, **DataList**, or **DataGrid** control, expand the **Container** node, which references the data source for the parent control. Expand the **DataItem** node and then select the column to bind to. When the control runs, the **DataItem** will contain the record currently being processed by the parent container.

     > **Note** The objects available in the **Simple Binding** tree are these: the **Page** object; any data source the derives from the **Component** class; any objects instantiated in the page's **InitializeComponent** method; and any objects that implement the IEnumerable interface.

   When you select a data source and member, a data-binding expression is constructed and displayed in the disabled **Custom binding expression** box below.

4. If you are working with a property that is of type **String**, and you want to format the results of the expression, select a formatting expression from the **Format** list.
5. If you want to create your own data-binding expression or modify one generated by selections in the **Simple binding**, choose **Custom binding expression**.

   The editing box is enabled and you can type or edit the expression.

   > **Note** You can edit the binding expression in HTML view as well.

6. Repeat Steps 2 through 5 for any other properties you want to bind.
7. Click **OK** to close the dialog box.

   In the Properties window, a data-binding glyph ( ) appears in the property name box to indicate that the property is data bound.

8. Add code to the Web Forms page to call the control's or the page's DataBind method.

Note You generally do not want to call the **DataBind** method on each round trip (that is, in the page initialization without checking for a post back), because doing so replaces the values in controls.

You can also specify data binding by editing the control declaration in HTML view of the Web Forms Designer.

To data bind single-value controls in HTML view

1. Create a data-binding expression and assign it as the value for a property (attribute). The expression's syntax is:

```
<%# expression %>
```

   The following example shows a data-binding expression. The expression gets the value of the `au_lname` column from the first record of a data view and assigns it to the **Text** property of a **TextBox** Web control.

```
<asp:TextBox id="TextBox1" runat="server"
   Text='<%# DataView1(0)("au_lname") %>'>
</asp:TextBox>
```

   Note For more information, see Data-Binding Expressions for Web Forms Pages and Data Binding Expression Syntax.

2. Add code to the Web Forms page to call the control's or the page's DataBind method.

   Note You generally do not want to call the **DataBind** method on each round trip (that is, in the page initialization without checking for a post back), because doing so replaces the values in controls.

Introduction to Data Access in Web Forms Pages | Data Binding Expression Syntax | Multi-Record and Single-Value Data Binding for Web Forms Pages | Data Binding HTML Server Controls

Data Binding HTML Server Controls

Visual Studio supports data binding for HTML server controls — for example, the HtmlButton and HtmlInputText controls — differently than it does Web server controls such as the **DataList**, **DataGrid**, and **TextBox** controls.

To data bind an HTML server control

- Set the property to bind to a data-binding expression. For details, see Data-Binding Expressions for Web Forms Pages. The expression should resolve to a single value.

  You can set HTML server control properties in the Properties window or in HTML view. If you use the Properties window, enter the data-binding expression without quotation marks around it. In HTML view, put quotation marks around the expression.

  > **Note** If you set the **value** property of a control such as the **HtmlInputText** control, the data-binding expression will appear as the control's text or caption at design time. However, at run time the expression will be evaluated and the result will be displayed instead.

  The following example shows what an **HtmlInputText** control might look like in HTML view after you have bound it to an author's name. The binding assumes that the page contains a data view called `DataView1` that displays information from an `authors` table. The expression gets the `au_lname` value from the first (number zero) record returned by the data view.

```
<INPUT id="Text1"
   type="text"
   name="Text1"
   runat="server"
   value='<%# DataBinder.Eval(DataView1, "[0].au_lname") %>'
>
```

Because the HtmlSelect server control (the HTML **Listbox** and **Dropdown** controls) can display multiple records, it supports special data-binding properties and the data-binding procedure is slightly different.

To data bind an HtmlSelect server control

1. Set the control's DataSource property to a data-binding expression that resolves to multiple values. For details, see Data-Binding Expressions for Web Forms Pages. A typical value is the name of a dataset instance on your page.

   > **Tip** You can set properties in the Properties window or in HTML view. If you use the Properties window, enter them without quotation marks. In HTML view, put quotation marks around the values.

2. If the data source contains multiple members (for example, if you are binding to a dataset with multiple tables in it), set the control's DataMember property to the name of the member to use.
3. If the member contains multiple fields, set the control's DataTextField property to the name of the field to display. For example, this is often the name of a column in a data table.
4. If you want to return a different value than what the user selects (for example, the control displays names but you want to return ID numbers), set the control's DataValueField property.

   The following example shows what an **HtmlSelect** control might look like in HTML view after you have bound it to the authors table in a dataset instance called `DsAuthors1`. The control displays the value of the `au_lname` column and when the user makes a selection, it returns the value of the `au_id` column.

```
<SELECT id="Select1" size="2" name="Select1" runat="server"
   DataSource="<%# DsAuthors1 %>"
   DataMember="authors"
   DataTextField="au_lname"
   DataValueField="au_id">
      <OPTION></OPTION>
</SELECT>
```

Data-Binding Expressions for Web Forms Pages | Controls You Can Use on Web Forms Pages | ASP.NET Server Controls Recommendations

Data Binding Single-Value Web Server Controls at Run Time

If you want to assign data values to a control property at run time, you can respond to a data-binding event that is raised by the control. In the event code, you can perform whatever logic is required to assign property values.

> **Note** At design time, you can create data-binding expressions that are evaluated at run time to assign values to control properties. For details, see Data Binding Single-Value Web Server Controls at Design Time.

To data bind single-value controls at run time

1. Make sure that code in your Web Forms page calls the DataBind method of either the control you are working with or of the page. The data-binding event will be raised in response to this method call.

   > **Note** You generally do not want to call the **DataBind** method on each round trip (that is, in the page initialization without checking for a post back), because doing so replaces the values in controls.

2. Create an event handler for the control's DataBinding event.
3. In the event handler, add code to assign values to the control's properties as required.

The following example shows how to perform simple data binding at run time. The Web Forms page contains two **TextBox** Web server controls that display information from the titles table in the SQL Server pubs database. Previous and Next buttons set a "record position" variable that is stored in session state. Whenever the user clicks these buttons to change the record position, the page's **DataBind** method is called, which raises the event used to fill the text boxes.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, ByVal e _
   As System.EventArgs) Handles MyBase.Load
        SqlDataAdapter1.Fill(DsTitles1)
        If Not (Me.IsPostBack) Then
            Session("RecordPos") = 0
            Me.DataBind()
        End If
End Sub

Private Sub btnNext_Click(ByVal sender As System.Object, ByVal e _
   As System.EventArgs) Handles btnNext.Click
   Dim RecordPos As Integer = CType(Session("RecordPos"), Integer)
   RecordPos += 1
   If RecordPos > DsTitles1.titles.Count Then
       RecordPos -= 1
   End If
   Session("RecordPos") = RecordPos
   Me.DataBind()
End Sub

Private Sub btnPrevious_Click(ByVal sender As System.Object, ByVal e _
   As System.EventArgs) Handles btnPrevious.Click
   Dim RecordPos As Integer = CType(Session("RecordPos"), Integer)
   If RecordPos > 0 Then
       RecordPos -= 1
   End If
   Session("RecordPos") = RecordPos
   Me.DataBind()
End Sub

Private Sub TextBox1_DataBinding(ByVal sender As Object, ByVal e _
   As System.EventArgs) Handles TextBox1.DataBinding
   Dim RecordPos As Integer = CType(Session("RecordPos"), Integer)
   TextBox1.Text = DsTitles1.titles(RecordPos).title_id
   TextBox2.Text = DsTitles1.titles(RecordPos).title
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
```

```
   sqlDataAdapter1.Fill(dsTitles1);
   if (!IsPostBack)
   {
Session["RecordPos"] = 0;
this.DataBind();
   }
}

private void btnNext_Click(object sender, System.EventArgs e)
{
    int RecordPos = (int) Session["RecordPos"];
    RecordPos++;
    if (RecordPos > dsTitles1.titles.Count)
    {
        RecordPos--;
    }
    Session["RecordPos"] = RecordPos;
    this.DataBind();
}

private void btnPrevious_Click(object sender, System.EventArgs e)
{
    int RecordPos = (int) Session["RecordPos"];
    if (RecordPos > 0)
    {
        RecordPos--;
    }
    Session["RecordPos"] = RecordPos;
    this.DataBind();
}

private void TextBox1_DataBinding(object sender, System.EventArgs e)
{
    int RecordPos = (int) Session["RecordPos"];
    TextBox1.Text = dsTitles1.titles[RecordPos].title_id;
    TextBox2.Text = dsTitles1.titles[RecordPos].title;
}
```

The following example binds a **Label** control to a value returned by executing a SQL command. The command object (which is explicitly for a SQL Server, as indicated by the named parameter) has previously been defined with a single parameter called `@empid`.

The user enters an employee ID and clicks a button. The button calls the **Label** control's **DataBind** method, which in turn raises the **DataBinding** event. In the event handler, the code gets the employee ID, sets it as a parameter for a **SqlCommand** object, and runs the command's SQL statement. The command returns a data reader object with one record in it, which the code reads and displays in the label.

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

```
' Visual Basic
Private Sub btnLogin_Click(ByVal sender As System.Object, ByVal e _
   As System.EventArgs) Handles btnLogin.Click
   Label1.DataBind()
End Sub

    Private Sub Label1_DataBinding(ByVal sender As Object, ByVal e _
       As System.EventArgs) Handles Label1.DataBinding
        SqlCommand1.Parameters("@empid").Value = LoginID.Text
        SqlCommand1.CommandText = _
           "SELECT emp_id, fname, lname FROM employee WHERE (emp_id = @empid)"
        SqlCommand1.CommandType = CommandType.Text
        Dim dr As System.Data.SqlClient.SqlDataReader
        SqlConnection1.Open()
        dr = SqlCommand1.ExecuteReader()
        If dr.Read() Then
```

```
            Label1.Text = "Welcome, " & CType(dr(1), String) & " " & CType(dr(2), String)
        Else
            Label1.Text = "Login not successful."
        End If
        dr.Close()
        SqlConnection1.Close()
    End Sub

// C#
private void btnLogin_Click(object sender, System.EventArgs e)
{
   Label1.DataBind();
}

private void Label1_DataBinding(object sender, System.EventArgs e)
{
   sqlCommand1.Parameters["@empid"].Value = LoginID.Text;
   sqlCommand1.CommandText =
      "SELECT emp_id, fname, lname FROM employee WHERE (emp_id = @empid)";   sqlCommand1.Comm
andType = CommandType.Text;
   System.Data.SqlClient.SqlDataReader dr;
   sqlConnection1.Open();
   dr = sqlCommand1.ExecuteReader();
   if (dr.Read())
   {
      Label1.Text = "Welcome, " + dr[1] + " " + dr[2];
   }
   else
   {
      Label1.Text = "Login not successful."
   }
   dr.Close();
   sqlConnection1.Close();
}
```

ASP.NET Server Controls

Server controls are specifically designed to work with Web Forms pages. They differ from controls for Windows applications because they work within the ASP.NET page framework. Because of this, server controls feature unique design considerations. The topics listed here provide background information on what server controls are and how they work.

In This Section

Introduction to ASP.NET Server Controls
Describes the general types of server controls and how they differ.
Creating and Programming ASP.NET Server Controls
Lists topics that provide the information about how to work with these controls.
Web Forms Validation
Lists topics that provide information on how to use the validation controls to verify user input on a Web Forms page.
Client Script in Web Forms Pages
Describes how you can combine client (browser) script with server-based code in a Web Forms page.
Controls You Can Use on Web Forms Pages
Links to a description of each type of ASP.NET server control.
Web User Controls and Web Custom Controls
Provides an overview of user controls (controls you create as Web Forms pages and then embed in other Web Forms pages) and of custom controls (controls you build by deriving from the base Web Forms control class).

Related Sections

Web Forms Pages
Lists topics pertaining to Web Forms generally.
ASP.NET Server Controls by Function

Provides suggestions for when to use each type of ASP.NET server control and why.

Code for Web Forms Controls

This topic is designed to help you find code that demonstrates how to perform common programming tasks with Web Forms controls.

Note For tasks that pertain to Web Forms pages generally, see Code for Web Applications.

The following categories are represented in the list below:

• Adding Controls to a Page • Properties, Attributes, and Styles • Validation • Templates • AdRotator Control • Button Control • Calendar Control • CheckBox, RadioButton Controls • DataGrid Control	• DataList, Repeater Controls • ListBox, DropDown, CheckBoxList, RadioButtonList Controls • Placeholder Control • Table, TableRow, TableCell Controls • TextBox Control • User Controls and Custom Controls • XML Control • Related Code Examples

You can also find sample code for Web Forms controls in the following locations:

- Web Applications Example Topics
- Web Forms Controls Example Topics
- Visual Basic Sample Applications
- Visual Basic QuickStarts and Other Samples
- .NET Framework Reference Information
- Developing ASP.NET Server Controls

Adding Controls to a Page

Example of...

Code Examples for Visual Basic Programmers

Introduction to ASP.NET Server Controls

When you create Web Forms pages, you can use these types of controls:

- **HTML server controls** HTML elements exposed to the server so you can program them. HTML server controls expose an object model that maps very closely to the HTML elements that they render.
- **Web server controls** Controls with more built-in features than HTML server controls. Web server controls include not only form-type controls such as buttons and text boxes, but also special-purpose controls such as a calendar. Web server controls are more abstract than HTML server controls in that their object model does not necessarily reflect HTML syntax.
- **Validation controls** Controls that incorporate logic to allow you to test a user's input. You attach a validation control to an input control to test what the user enters for that input control. Validation controls are provided to allow you to check for a required field, to test against a specific value or pattern of characters, to verify that a value lies within a range, and so on.
- **User controls** Controls that you create as Web Forms pages. You can embed Web Forms user controls in other Web Forms pages, which is an easy way to create menus, toolbars, and other reusable elements.

> **Note** You can also create output for mobile devices. To do so, you use the same ASP.NET page framework, but you create Mobile Web Forms instead of Web Forms pages and use controls specifically designed for mobile devices. For details, see Creating ASP.NET Mobile Web Applications.

You can use all types of controls on the same page. The following sections provide more detail about ASP.NET server controls. For more information about validation controls, see Web Forms Validation. For information about user controls, see Introduction to Web User Controls.

> **Note** In some situations, server controls require client script in order to function properly. If a user has disabled scripting in the browser, the controls might not function as you intend. For details, see ASP.NET Server Controls and Browser Capabilities.

HTML Server Controls

HTML server controls are HTML elements containing attributes that make them visible to — and programmable on — the server. By default, HTML elements on a Web Forms page are not available to the server; they are treated as opaque text that is passed through to the browser. However, by converting HTML elements to HTML server controls, you expose them as elements you can program on the server.

The object model for HTML server controls maps closely to that of the corresponding elements. For example, HTML attributes are exposed in HTML server controls as properties.

Any HTML element on a page can be converted to an HTML server control. Conversion is a simple process involving just a few attributes. As a minimum, an HTML element is converted to a control by the addition of the attribute RUNAT="SERVER". This alerts the ASP.NET page framework during parsing that it should create an instance of the control to use during server-side page processing. If you want to reference the control as a member within your code, you should also assign an ID attribute to the control.

The page framework provides predefined HTML server controls for the HTML elements most commonly used dynamically on a page: forms, the HTML <INPUT> elements (text box, check box, Submit button, and so on), list box (<SELECT>), table, image, and so on. These predefined HTML server controls share the basic properties of the generic control, and in addition, each control typically provides its own set of properties and its own event.

HTML server controls offer the following features:

- An object model that you can program against on the server using the familiar object-oriented techniques. Each server control exposes properties that allow you to manipulate the control's HTML attributes programmatically in server code.
- A set of events for which you can write event handlers in much the same way you would in a client-based form, except that the event is handled in server code.
- The ability to handle events in client script.
- Automatic maintenance of the control's state. If the form makes a round trip to the server, the values that the user entered into HTML server controls are automatically maintained when the page is sent back to the browser.
- Interaction with validation controls so you can easily verify that a user has entered appropriate information into a control.
- Data binding to one or more properties of the control.
- Support for HTML 4.0 styles if the Web Forms page is displayed in a browser that supports cascading style sheets.
- Pass-through of custom attributes. You can add any attributes you need to an HTML server control and the page framework

will read them and render them without any change in functionality. This allows you to add browser-specific attributes to your controls.

For details about how to convert an HTML element to an HTML server control, see Adding HTML Server Controls to a Web Forms Page.

Web Server Controls

Web server controls are a second set of controls designed with a different emphasis. They do not map one-to-one to HTML server controls. Instead, they are defined as abstract controls in which the actual HTML rendered by the control can be quite different from the model that you program against. For example, a **RadioButtonList** Web server control might be rendered in a table or as inline text with other HTML.

Web server controls include traditional form controls such as buttons and text boxes as well as complex controls such as tables. They also include controls that provide commonly used form functionality such as displaying data in a grid, choosing dates, and so on.

Web server controls offer all of the features described above for HTML server controls (except one-to-one mapping to HTML elements) and these additional features:

- A rich object model that provides type-safe programming capabilities.
- Automatic browser detection. The controls can detect browser capabilities and create appropriate output for both basic and rich (HTML 4.0) browsers.
- For some controls, the ability to define your own look for the control using templates.
- For some controls, the ability to specify whether a control's event causes immediate posting to the server or is instead cached and raised when the form is submitted.
- Ability to pass events from a nested control (such as a button in a table) to the container control.

At design time in HTML view, the controls appear in your page in a format such as:

```
<asp:button attributes runat="server"/>
```

The attributes in this case are not those of HTML elements. Instead, they are properties of the Web control.

When the Web Forms page runs, the Web server control is rendered on the page using appropriate HTML, which often depends not only on the browser type but also on settings that you have made for the control. For example, a **TextBox** control might render as an <INPUT> tag or a <TEXTAREA> tag, depending on its properties.

Detailed how-to and reference documentation is available for each control separately. For more information, see Controls You Can Use on Web Forms Pages.

ASP.NET Server Controls by Function

The ASP.NET server controls are listed here according to general function. The following sections individually provide details about Web server controls, HTML server controls, and validation controls.

> **Note** For more about the differences between Web and HTML server controls, see Introduction to ASP.NET Server Controls.

Web Server Controls

Web server controls include traditional user-entry controls as well as special-purpose controls such as a calendar. All Web server controls can be bound to a data source.

> **Note** You can also create output for mobile devices. To do so, you use the same ASP.NET page framework, but you create Mobile Web Forms instead of Web Forms pages and use controls specifically designed for mobile devices. For details, see Creating ASP.NET Mobile Web Applications.

The Web server controls are listed below according to their function.

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

Function	Control	Description
Text display (read only)	Label	Displays text that users cannot directly edit.
Text edit	TextBox	Displays text that can be edited by users at run time or changed programmatically.
Selection from a list	DropDownList	Allows users to select from a list that appears when the user clicks a button.
	ListBox	Displays a list of choices. Optionally, the list can allow multiple selections.
Graphics display	Image	Displays an image.
	AdRotator	Displays a sequence (predefined or random) of images.
Value setting	CheckBox	Displays a box that users can click to turn on and off.
	CheckBoxList	Creates a grouping of check boxes. The list control makes it easy to create check boxes using data binding.
	RadioButton	Displays a single button that can be turned on or off.
	RadioButtonList	Creates a grouping of radio buttons. Inside the group, only one button can be selected.
Date setting	Calendar	Displays a graphic calendar to allow users to select a date.
Commands **Note** These controls always cause the form to be posted to the server for processing.	Button	Performs a task.
	LinkButton	Like a **Button** control, but has the appearance of a hyperlink.
	ImageButton	Like a **Button** control, but incorporates an image instead of text.
Navigation	HyperLink	Creates a Web navigation link.
Table manipulation	Table	Creates a table.
	TableCell	Creates an individual cell within a table row.
	TableRow	Creates an individual row within a table.
Grouping other controls	CheckBoxList	Creates a collection of check boxes.
	Panel	Creates a borderless division on the form that serves as a container for other controls.
	RadioButtonList	Creates a grouping of radio buttons. Inside the group, only one button can be selected.

Selection from a list	Repeater	Displays information from a data source using a set of HTML elements and controls you specify, repeating the elements once for each record in the data set.
	DataList	Like the **Repeater** control, but with more formatting and layout options, including the ability to display information in a table. The **DataList** control also allows you to specify editing behavior.
	DataGrid	Displays information, usually data-bound, in tabular form with columns. Provides mechanisms to allow editing and sorting.
Place holding	PlaceHolder	Enables you to place an empty container control in the page and then dynamically add child elements to it at run time.
	Literal	Renders static text into a Web page without adding any HTML elements.
	XML	Reads XML and writes it into a Web Forms page at the location of the control.

HTML Server Controls

HTML server controls map directly to HTML elements. The controls listed in this section are predefined controls. However, any HTML element can be made into a control; in that case, the control supports a generic set properties and methods. All HTML server controls can be bound to a data source.

Function	Control	Description
Forms	HtmlForm	Defines an HTML form. The values of controls within the form are posted to the server when the form is submitted.
Text edit	HtmlInputText	Displays text that can be edited by users at run time, or changed programmatically.
	HtmlTextArea	Displays large quantities of text. Used for multi-line text entry and display.
Commands **Note** These controls always cause the form to be posted to the server for processing.	HtmlAnchor	Enables Web navigation.
	HtmlButton	Performs a task. This control can contain any arbitrary HTML, and therefore it is very flexible in look and feel. However, it is not compatible with all browsers.
	HtmlInputButton	Performs a task. This button is supported on all browsers.
	HtmlInputImage	Like a button, but displays a graphic.
Selection from a list	HtmlSelect	Displays a list of text and graphical items (icons).
Graphics display	HtmlImage	Displays an image.
Information storage	HtmlInputHidden	Stores state information for a form (information that needs to be available with each round trip to the server).
Navigation	HtmlAnchor	Creates a Web navigation link.
Value setting	HtmlInputCheckbox	Creates a box that users can click to turn on and off. The **CheckBox** control includes a label.
	HtmlInputRadioButton	Displays a button that can be turned on or off. Radio buttons are typically used to allow the user to select one item from a short list of fixed options.
Table manipulation	HtmlTable	Creates a table.
	HtmlTableRow	Creates an individual row within a table.
	HtmlTableCell	Creates an individual cell within a table row.
File transfer	HtmlInputFile	Allows users to specify files to upload to a server. (The server must allow uploads.)
Other functions	HtmlGenericControl	Creates a basic object model (properties, methods, events) for any HTML element converted to a control.

Validation Controls

Validation controls provide you with a way to check user input in Web or HTML server controls. The following table lists the type

of validation controls you can use in Web Forms. For more details, see Web Forms Validation.

Type of validation	Control to use	Description
Required entry	**RequiredFieldValidator**	Ensures that the user does not skip an entry.
Comparison to a value	**CompareValidator**	Compares a user's entry against a constant value or a property value of another control using a comparison operator (less than, equal, greater than, and so on).
Range checking	**RangeValidator**	Checks that a user's entry is between specified lower and upper boundaries. You can check ranges within pairs of numbers, alphabetic characters, and dates. Boundaries can be expressed as constants or as values derived from another control.
Pattern matching	**RegularExpressionValidator**	Checks that the entry matches a pattern defined by a regular expression. This type of validation allows you to check for predictable sequences of characters, such as those in social security numbers, e-mail addresses, telephone numbers, postal codes, and so on.
User-defined	**CustomValidator**	Checks the user's entry using validation logic that you code yourself.
None	**ValidationSummary**	Displays the error messages of all other validation controls on the page in a single unified summary.

Creating and Programming ASP.NET Server Controls

ASP.NET server controls expose a unique programming model that differs from that used with controls on Windows Forms. The topics in this section provide the information you need to understand how to work with these controls.

In This Section

Adding Web Server Controls to a Web Forms Page
Describes how to add Web server controls (as opposed to HTML server controls) to a page.
Adding HTML Server Controls to a Web Forms Page
Describes how to add HTML server controls (as opposed to Web server controls) to a page.
Converting HTML Server Controls to HTML Elements
Describes how to convert existing HTML elements on a page into controls.
Adding Controls to a Web Forms Page Programmatically
Describes how to instantiate server controls dynamically in code.
ASP.NET Server Controls and CSS Styles
Provides information on how server controls interact with cascading style sheets (CSS) and how you can set styles for controls.
Customizing the Appearance of ASP.NET Server Controls Using Styles
Describes how to manipulate CSS styles in ASP.NET server controls.
Web Server Controls Templates
Provides information on using templates — snippets of HTML combined with controls — to define individual elements of a complex control (for example, the header, footer, and selected row in a **DataList** control).
Creating Web Server Control Templates
Describes how to define templates in either the Web Forms Designer or directly in the .aspx file.
Creating Web Server Control Templates Dynamically
Describes how to create a template at run time and assign it to a **DataList** or **Repeater** control.
Creating Templates Programmatically in the DataGrid Control
Describes how to create a template column at run time for a **DataGrid** control.
Setting ASP.NET Server Control Properties
Describes how to set properties using the Web Forms Designer or by setting properties in the .aspx file.
Setting Web Server Control Properties Programmatically
Describes how to set properties such as colors, units (pixels) in code for Web server controls (as opposed to HTML server controls).
Setting HTML Server Control Properties Programmatically
Describes how to set properties of HTML server controls (as opposed to Web server controls) in code.
Specifying Whether Controls Post to the Server
Describes how to specify whether events in controls such as the **CheckBox** control cause a form to be sent to the server or, instead, cache event information until the form is posted some other way.
Web Forms Control Identification
Discusses how the ASP.NET page framework provides mechanisms to ensure that controls on a page and in an application have unique identifiers.
Referencing Controls in Web Forms Pages
Explains how to get access to controls when you are working with naming containers and child controls.

Describes how to create a template column at run time for a **DataGrid** control.
Introduction to Validating User Input in Web Forms
Describes how you can validate user input made with ASP.NET server controls.

Adding Web Server Controls to a Web Forms Page

You add controls to a Web Forms page much the same way you add any HTML element. You can either use the Visual Studio Web Forms Designer and add a control from the Toolbox, or type the element representing the control into the HTML.

> **Note** You can also add controls programmatically at run time. For details, see Adding Controls to a Web Forms Page Programmatically.

Adding Web Server Controls Using the Web Forms Designer

The Toolbox contains tabs with controls that you can use when you design a Web Forms page.

To add a Web server control to a Web Forms page

1. Switch to Design view.
2. From the **Web Forms** tab of the Toolbox, drag the control onto the form.

   A glyph ( ) appears on the control in Design view to indicate that it is a server-based control.

   > **Note** By default, the Web Forms page uses Grid layout, and you place controls at absolute positions on the page (using x and y coordinates). If you want to use linear layout, in which the page elements flow as in a word processing document, you can change the page's **pageLayout** property, or include a **Flow Layout Panel** HTML server control. For more details, see Positioning HTML Elements in Design View.

Adding Web Server Controls using ASP.NET Syntax

You can add a control to a page by declaring it directly in the .aspx file.

> **Note** For background information about controls for Web Forms pages, see Introduction to ASP.NET Server Controls.

To add a control using ASP.NET syntax

1. Switch to HTML view.
2. Type the element representing the control into the .aspx file. In Visual Studio, you do this in HTML view. The exact syntax you use depends on the control you are adding, but in general the following applies:

   - Controls must include the attribute **runat="server"**.
   - Set the control's **ID** attribute unless the control is part of a complex control and will be repeated (as in the **Repeater**, **DataList**, and **DataGrid** controls).
   - Web server controls are declared with an XML tag that references the **asp** namespace.
   - Control declarations must be properly closed. You can specify an explicit closing tag, or, if the control has no child elements, you can specify a self-closing tag. The only exceptions are HTML input controls that cannot have child elements, such as the input controls (for example, HtmlInputText, HtmlImage, and HtmlButton).
   - Control properties are declared as attributes.

     The following examples show typical declarations for Web server controls:

```
<!-- Textbox Web server control -->
<asp:textbox id=TextBox1 runat="Server" Text=""></asp:textbox>

<!-- Same, but with self-closing element -->
<asp:textbox id=Textbox1 runat="Server" Text="" />

<!-- Web DropDownList control, which contains subelements -->
<asp:DropDownList id=DropDown1 runat="server">
   <asp:ListItem Value="0">0</asp:ListItem>
   <asp:ListItem Value="1">1</asp:ListItem>
   <asp:ListItem Value="2">2</asp:ListItem>
   <asp:ListItem Value="3">3</asp:ListItem>
</asp:DropDownList>
```

```
<asp:Repeater id=Repeater2 runat="server">
   <HeaderTemplate>
       Company data:
   </HeaderTemplate>
   <ItemTemplate>
       <asp:Label runat="server"
           Font-Name="verdana" Font-Size="10pt"
           Text='<%# Container.DataItem.Name %>' />
       ( <asp:Label runat=server
             Font-Name="verdana" Font-Size="10pt"
             Text='<%# Container.DataItem.Ticker %>'/>
        )
   </ItemTemplate>
   <SeparatorTemplate>
       ,
   </SeparatorTemplate>
</asp:Repeater>
```

For information about the declarative syntax for a specific Web server control, search in the Index in Help for "Web controls" and choose the name of the control you want to use.

Note If the Web Forms Designer cannot render a Web server control correctly, it displays a grey box with the text "Error Creating Control." This often means that the ASP.NET syntax of the control is incorrect — for example, if the
runat="server"
attribute is missing in a Web server control element, you will see this error. Point to the information icon ( ); a ToolTip is displayed with details about the error.

Adding HTML Server Controls to a Web Forms Page

Adding HTML server controls is like adding any HTML element, except that you convert the element to a control so that you can work with it in server code.

> **Note** For background information about controls for Web Forms pages, see Introduction to ASP.NET Server Controls.

Adding HTML Server Controls Using the Web Forms Designer

Adding HTML server controls to a Web Forms page is a two-step process.

To add an HTML server control to a Web Forms page

1. From the **HTML** tab of the Toolbox, drag an HTML element onto the page.
2. Convert the element to a control by right-clicking it and choosing **Run As Server Control**.

   The Web Forms Designer adds the attribute `runat="server"` to the element, which alerts the server to treat the element as a control. A glyph (▶) appears on the control in Design view to indicate that it is a server-based control.

   > **Note** By default, the Web Forms page uses Grid layout, and you place controls at absolute positions on the page (using x and y coordinates). If you want to use linear layout, in which the page elements flow as in a word processing document, you can change the page's **pageLayout** property, or include a **Flow Layout Panel** HTML server control. For more details, see Positioning HTML Elements in Design View.

Adding HTML Server Controls using ASP.NET Syntax

You can add an HTML server control to a page by declaring it directly in the .aspx file.

To add an HTML server control using ASP.NET syntax

1. Switch to HTML view.
2. Type the HTML syntax of the element you want to use as a control. Include the normal HTML syntax for the element, and in addition, do the following:

   - Set the control's **ID** attribute (property) to a unique value for that page, unless the control is part of a complex control and will be repeated (as in **Repeater**, **DataList**, and **DataGrid** controls).
   - Set the **runat="server"** attribute to convert the element to a control.

   The following example shows how to declare an HtmlInputText control, an HtmlInputButton control, and an HtmlAnchor control:

```
<input id="Name" type=text size=40 runat="server">
<input type=submit id="Enter" value="Enter" runat="server">
Click <a id="Anchor1" runat="server" href="more.html">More </a> to see the next page.
```

For information about the declarative syntax for a specific HTML server control, search in the Index in Help for "HTML server controls" and choose name of the control you want to use.

Converting HTML Server Controls to HTML Elements

If you no longer need to program an HTML server control in server code, you should convert it back to a plain HTML element. Each HTML server control in a form uses resources, so it is a good practice to minimize the number of controls that the Web Forms page has to work with.

To convert an HTML server control to an HTML element

- In Design view or in the Document Outline window, right-click the control and clear the check mark next to **Run As Server Control**.

You can also perform the conversion by editing HTML directly.

To convert an HTML server control to a HTML element using ASP.NET syntax

- In HTML view, remove the attribute `runat="server"` from the control's tag.

  You do not have to remove the ID attribute. You want to be especially careful not to remove the ID attribute if there is client script that references the element.

Adding Controls to a Web Forms Page Programmatically

There are times when it is more practical to create a control at run time than at design time. For example, imagine a search results page in which you want to display results in a table. Because you do not know how many items will be returned, you want to dynamically generate one table row for each returned item.

> **Note** Existing controls can often provide the functionality you get from creating controls dynamically. For example, controls such as the **Repeater**, **DataList**, and **RadioButtonList** controls can dynamically create rows or other control elements when the page runs.

In order to programmatically add a control to a page, there must be a container for the new control. For example, if you are creating table rows, the container is the table. If there is no obvious control to act as container, you can use a **Placeholder** or **Panel** Web server control.

In some instances, you might want to create both static text and controls. To create static text, you can use either a **Literal** or a **Label** Web server control. You can then add these controls to the container as you would any other control.

> **Note** Manipulating controls programmatically is often used when creating composite controls. For details, see Developing a Composite Control.

Dynamic Controls and View State

When a control is created dynamically at run time, some information about the control is stored in the view state that is rendered with the page. When the page is posted back to the server, however, non-dynamic controls (those defined on the page) are instantiated in the **Page.Init** event and view state information is loaded before the dynamic controls can be recreated (generally in the **Page_Load** handler). Effectively, before the dynamic controls are recreated, view state is temporarily out of sync with the page's controls. After the **Page_Load** event has run, but before control event handling methods are called, the remaining view state information is loaded into the dynamically created controls.

In most scenarios, this view state processing model works fine. Typically, you add dynamic controls to the end of a container's collection of controls. The view state information stored for the dynamic controls is therefore extra information at the end of the view state structure for the appropriate container, and the page can ignore it until after the controls are created.

However, view state information about dynamically created controls can be a problem in two scenarios:

- If you insert dynamic controls between existing controls.
- If you insert controls dynamically and then reinsert them during a round trip, but with different values.

If you insert dynamic controls between existing controls, the dynamic control's view state information is inserted into the corresponding location of the view state structure. When the page is posted and the view state is loaded, the dynamic control does not yet exist; therefore, the extra information in view state does not correspond to the right control. The result is usually an error indicating an invalid cast.

If you reinsert controls with each round trip, each generation of dynamically created controls will pick up property values from the view state of the preceding set of controls. In many cases, you can avoid this problem by setting the EnableViewState property of the container control to **false**. In that case, no information about the dynamic controls is saved, and there is no conflict with successive versions of the controls.

For details about view state, see Web Forms Page Processing, Introduction to Web Forms State Management, and Control.ViewState.

To add a control to a Web Forms page programmatically

1. Create an instance of the control and set its properties:

```
' Visual Basic
Dim myLabel As Label = New Label()
myLabel.Text = "Sample Label"

// C#
Label myLabel = new Label();
myLabel.Text = "Sample Label";
```

> **Tip** Controls are typically added to the page during the page's load stage. For details about page stages, see

Web Forms Page Processing.

2. Add the new control to the **Controls** collection of a container already on the page:

```
' Visual Basic
Panel1.Controls.Add(myLabel)

// C#
Panel1.Controls.Add(myLabel);
```

> **Note** Because **Controls** is a collection, it is possible to use the AddAt method to place the new control at a specific location — for example, in front of other controls. However, this can introduce errors into the page. For details, see "Dynamic Controls and View State" earlier in this topic.

The following example shows the event handler for the **SelectedIndexChanged** event of a control called "DropDownList1". The handler creates as many label controls as the user has selected from the drop-down list. The labels display the word "Label" plus a counter. The container for the controls is a **Placeholder** Web server control called "Placeholder1."

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

```
' Visual Basic
Private Sub DropDownList1_SelectedIndexChanged(ByVal sender As System.Object, ByVal e As
System.EventArgs) Handles DropDownList1.SelectedIndexChanged
   Dim i As Integer
   Dim numlabels As Integer
   ' Get the number of labels to create.
   numlabels = CInt(DropDownList1.SelectedItem.Text)
   For i = 1 To numlabels
      Dim myLabel As Label = New Label()
      ' Set the label's Text and ID properties.
      myLabel.Text = "Label " & i
      myLabel.ID = "Label" & i
      PlaceHolder1.Controls.Add(myLabel)
      ' Add a spacer in the form of an HTML <BR> element
      Dim spacer As LiteralControl = New LiteralControl("<br>")
      PlaceHolder1.Controls.Add(spacer)
   Next
End Sub

// C#
private void DropDownList1_SelectedIndexChanged(object sender, System.EventArgs e)
{
   // Get the number of labels to create.
   int numlabels = System.Convert.ToInt32(DropDownList1.SelectedItem.Text);
   for (int i=1; i<=numlabels; i++)
   {
      Label myLabel = new Label();
      // Set the label's Text and ID properties.
      myLabel.Text = "Label" + i.ToString();
      myLabel.ID = "Label" + i.ToString();
      PlaceHolder1.Controls.Add(myLabel);
      // Add a spacer in the form of an HTML <BR> element.
      PlaceHolder1.Controls.Add(new LiteralControl("<br>"));
   }
}
```

Setting Web Server Control Properties Programmatically | Setting HTML Server Control Properties Programmatically | ASP.NET Server Controls | Referencing Controls in Web Forms Pages

ASP.NET Server Controls and CSS Styles

You can control the look of controls by setting various appearance properties such as **ForeColor**, **BackColor**, **Height**, and **Width**. In addition, some controls support style objects that expose additional style-related settings.

> **Note** Web Forms pages (.aspx files) function as HTML pages at run time. You can therefore use cascading style sheets (CSS) to set the appearance of any elements on the page other than Web server controls. For details, see Applying a CSS Style to Another Web Page.

The sections below provide information about how style information is rendered to the browser and how to work with styles both at design time and programmatically.

Rendering Appearance Properties to the Browser

When the page runs, appearance properties are rendered according to the capabilities of the user's browser. If the user's browser supports cascading stylesheets (CSS), the appearance properties are rendered as style attributes of the HTML elements that make up the control. For example, if you create a **LinkButton** Web server control and set its ForeColor property to **Red**, its FontInfo.Bold property to **true**, and its FontInfo.Size property to **xx-small**, the control is rendered as the following if the user's browser supports stylesheets:

```
<a id="HyperLink1" style="color: Red; font-size: XX-Small; font-weight: bold;">HyperLink</a>
```

On the other hand, if the user's browser does not support styles, the control is rendered using other means, such as a <FONT> element. The following shows the rendering for the example from above, but for a browser that does not support styles:

```
<a id="HyperLink1"><b><font color="Red" size="1">HyperLink</font></b></a>
```

Other examples of properties that are rendered differently depending on the browser are **BorderWidth** and **BorderColor**.

Some appearance properties, such as **BorderStyle**, cannot be rendered without using styles. These properties are therefore ignored in downlevel browsers. For more information, see ASP.NET Server Controls and Browser Capabilities.

Control Style Objects

In addition to simple appearance properties such as **ForeColor** and **BackColor**, controls expose one or more style objects that encapsulate additional appearance properties. One example is the **Font** style property, which exposes an object of type **FontInfo** containing individual properties pertaining to the font, such as **Size**, **Name**, **Bold**, and so on.

Some controls expose style objects you can use to set the appearance of specific portions of the control. For example, the **Calendar** Web server control contains style objects such as DayStyle (individual days), SelectedDayStyle (a day, week, or month selected by the user), and WeekendDayStyle. Using the **SelectedDayStyle** style object, for example, you can set the **BackColor** and **ForeColor** properties of the day selected by the user.

Most style objects are of type **TableItemStyle**, because they are setting the attributes of table cells. The **Font** style object is of type **FontStyle**.

Precedence and Inheritance of Style Objects

In complex controls, style objects often inherit characteristics from other style objects. For example, in the **Calendar** control, the **SelectedDayStyle** object is based on the **DayStyle** object. If you do not explicitly set any properties for **SelectedDayStyle**, it inherits its characteristics from the **DayStyle** object.

This inheritance means that style-object properties you set have an order of precedence. For example, the following list shows the order of style-object properties for the **Calendar** control, with the highest precedence given to the settings on the object last on the list.

1. Appearance properties of the base Calendar control
2. **DayStyle** style object
3. **WeekendDayStyle** style object
4. OtherMonthDayStyle style object
5. **TodayStyle** style object
6. **SelectedDayStyle** style object

Controlling CSS Styles and Classes Directly

In addition to the appearance properties and style objects, controls expose two properties that allow you to manipulate CSS styles more directly: **CSSStyle** and **CSSClass**. The **CSSClass** property enables you to assign a stylesheet class to the control. The **CSSStyle** property enables you to set a string of style attributes to be written as-is to the control. Using the **CSSStyle** property allows you to set style attributes that are not exposed via other properties.

Settings you make in the **CSSStyle** property are not reflected in the corresponding individual appearance property. For example, if you set a string `background-color:red` in the **CSSStyle** property, the **BackColor** property is not also set to red, even though the control will render with a red background. Furthermore, if you set both appearance properties and the **CSSStyle** property, the individual appearance properties take precedence over the **CSSStyle** property.

Customizing the Appearance of ASP.NET Server Controls Using Styles

Some server controls allow you to customize the appearance of individual elements by setting properties of style objects. For example, in the **Calendar** Web server control, you can set the appearance of the selected day by setting properties of the SelectedDayStyle object. Similarly, in the **DataList** Web server control, you can set the appearance of individual items and selected items using properties of the ItemStyle and SelectedItemStyle objects.

Setting Style Properties in the Web Forms Designer

The Web Forms Designer provides tools that make it easy to set style properties.

To set style properties in the Web Forms Designer

1. In Design view, select the control that you want to set styles for.
2. In the Properties window, do the following:

   - Expand the style object and then set properties for that object. For example, to set properties for the **DataList** control's **ItemStyle** object, expand **ItemStyle** in the Properties window.

     –or–

   - If the control supports property builders (such as the DataList and DataGrid controls), click **Property Builder** at the bottom of the Properties window to open the **Properties** dialog box. Choose the **Format** option, choose a style object in the **Objects** list, and then set its properties.

Setting Style Properties

You can set style properties directly in the .aspx file in two ways.

To set style properties in the .aspx file

- Declare the style property using a convention of hyphenating the style object name and property:

```
<asp:Calendar ID="MyCalendar"
   SelectionMode="DayWeek"
   runat="server"
   TitleStyle-Backcolor="#3366ff"
   TitleStyle-ForeColor="White" />
```

  -or-

- Declare explicit elements in which you declare property elements of the appropriate data type:

```
<asp:Calendar id="MyCalendar"
   SelectionMode="DayWeek"
   runat="server">
   <TitleStyle BackColor="#3366ff"
               ForeColor="white" />
</asp:Calendar>
```

Note If the Web Forms Designer cannot render a Web server control correctly, it displays a grey box with the text "Error Creating Control." This often means that the ASP.NET syntax of the control is incorrect — for example, if the
runat="server"
attribute is missing in a Web server control element, you will see this error. Point to the information icon ( ); a ToolTip is displayed with details about the error.

Setting Style Properties Programmatically

You can set style properties of a control programmatically, which allows you to change the appearance of a control conditionally.

To set style properties programmatically

- Use the following hierarchical convention for specifying the style object and property you want to set:

```
Control.StyleObject.Property = value
```

  The following example shows how you might set the **BackColor** property for the **DayStyle** object of a **Calendar** control:

```
' Visual Basic
Calendar1.DayStyle.BackColor = Color.Green

// C#
Calendar1.DayStyle.BackColor = Color.Green;
```

You can also create a separate Style object and copy or merge the values of its properties to one of the styles on a control. This is a powerful way to apply the same styles to several different list objects in your project. In effect, you can create a virtual stylesheet as a **Style** object and then apply it to a series of controls.

To create a Style object and apply it to controls

1. Create an instance of the **Style** object and set its properties:

```
' Visual Basic
Dim s As Style = New Style()
s.BackColor = Color.Red

// C#
Style s = new Style();
s.BackColor = Color.Red;
```

2. Assign the **Style** object to a control using one of the following methods:

   - The CopyFrom method applies all settings from a **Style** object, including null ones.
   - The MergeWith method copies only the properties already set on the **Style** object, skipping **Style** properties that have not been set. Also, the **MergeWith** method will not overwrite any existing style elements.

   The following example shows how you might create a **Style** object, set one of its properties, and then apply it to two different control style objects, using each of the methods described:

```
' Visual Basic
' Apply all values in s, including nulls.
Calendar1.SelectedDayStyle.CopyFrom(s)
' Apply only values in s that are null in HeaderStyle.
DataGrid1.HeaderStyle.MergeWith(s)

// C#
// Apply all values in s, including nulls.
Calendar1.SelectedDayStyle.CopyFrom(s);
// Apply only values in s that are null in HeaderStyle.
DataGrid1.HeaderStyle.MergeWith(s);
```

Programming Web Forms | ASP.NET Server Controls and CSS Styles | Web Server Controls Templates | ASP.NET Server Controls | ASP.NET Server Controls and Browser Capabilities

Web Server Controls Templates

Most Web server controls have a default look and layout, which you can manipulate by setting properties or by using styles. Some Web server controls also allow you to customize their look by using templates.

A template is a set of HTML elements and controls that make up the layout for a particular portion of a control. For example, in the **DataList** Web server control you can use a combination of HTML elements and controls to create the layout for each row of the list. Similarly, the **DataGrid** Web server control has a default look for rows in the grid. However, you can customize the grid's look by defining different templates for individual rows, alternating rows, selected rows, and so on.

> **Note** Templates differ from styles. A template defines the content of a section of a control — for example, the contents of a row in the **DataList** control. Styles, on the other hand, specify the appearance of elements such as color, font, and so on. Styles can apply to the control as a whole (for example, to set the font for the **DataGrid** control) as well as to template items.

Templates consist of HTML and even embedded server controls. When the control runs in the Web Forms page, the control framework renders the contents of the template in place of the default HTML for the control.

Which Controls Support Templates?

Not all Web server controls support templates. For the most part, templates are supported by complex controls. In Visual Studio, this includes the **DataGrid**, **DataList**, and **Repeater** Web server controls. (In fact, the **Repeater** and **DataList** controls not only support templates, but require that you create templates to define their output). Controls that you acquire from other sources might also support templates.

Each control supports a slightly different set of templates that specify layouts for different portions of the control, such as the header, footer, item, and selected item. You can specify a template for any or all of these, depending on which ones you want to customize. In the **DataGrid** control, you can specify templates for columns (rather than rows).

The following table summarizes the Web server controls that support templates:

Control	Templates
Repeater	• HeaderTemplate • FooterTemplate • ItemTemplate • AlternatingItemTemplate • SeparatorTemplate
DataList	• HeaderTemplate • FooterTemplate • ItemTemplate • AlternatingItemTemplate • SeparatorTemplate • SelectedItemTemplate • EditItemTemplate
DataGrid	• HeaderTemplate • FooterTemplate • ItemTemplate (column) • EditItemTemplate (column) • Pager

Creating Templates

The Web Forms Designer includes a facility that allows you to lay out templates in a WYSIWYG way. You open a special template-editing mode that presents the control's templates in Design view. You can type HTML and drag controls from the Toolbox directly to the template you are editing.

You can also create templates directly in the .aspx file. Templates are created as XML declarations. The following example shows how you can display a list of employee names, phone numbers, and email addresses using templates in the **DataList** Web server

control. The layout of the employee information is specified in the ItemTemplate using data-bound controls.

```
<asp:datalist ID="DataList1" runat="server">
   <HeaderTemplate>
      Employee List
   </HeaderTemplate>
   <ItemTemplate>
      <asp:label id=Label1 runat="server"
         Text='<%# DataBinder.Eval(Container, "DataItem.EmployeeName")
         %>'></asp:label>
      <asp:label id=Label2 runat="server"
         Text='<%# DataBinder.Eval(Container, "DataItem.PhoneNumber")
         %>'></asp:label>
      <asp:Hyperlink id=Hyperlink1 runat="server"
         Text='<%# DataBinder.Eval(Container, "DataItem.Email") %>'
         NavigateURL='<%# DataBinder.Eval(Container, "DataItem.Link") %>'>
      </asp:Hyperlink>
   </ItemTemplate>
</asp:datalist>
```

Creating Web Server Control Templates | Creating Web Server Control Templates Dynamically | ASP.NET Server Controls | ASP.NET Server Controls and CSS Styles | Web Forms Data Binding | Creating Web Server Control Templates Dynamically | Creating Templates Programmatically in the DataGrid Control

Creating Web Server Control Templates

The **DataList**, **DataGrid**, and **Repeater** Web server controls allow you to specify templates, which are HTML elements that define the layout for a particular portion of the control. For example, in the **DataGrid** control, you can define templates for items, selected items, alternating items, and so on, so that each of these elements can have a custom look.

> **Note** For background information about templates, see Web Server Controls Templates.

Creating Templates in the Web Forms Designer

You can create templates directly from within the Web Forms Designer.

To create a template in the Web Forms Designer

1. Right-click the control, choose **Edit Template**, and then choose the type of template that you want to edit.

   For example, to edit the **Item**, **AlternatingItem**, **SelectedItem**, and **EditItem** templates for the **DataList** Web server control, choose **Item Templates**.

   The Web Forms Designer displays the control in template-editing mode.

2. Enter HTML text and drag controls into the template.
3. Edit controls you have added to templates as you would normal controls:

   - Select them and use the Properties window to set their properties.
   - Data bind them using the **DataBinding** dialog box. For details, see Introduction to Data Binding in Web Forms Pages.
   - Double-click the embedded controls to create an **ItemCommand** event handler for the container control. Events raised by embedded controls are bubbled to the container. For more details, see ASP.NET Server Control Event Model.

4. Repeat Steps 1 through 3 to edit other templates.
5. To finish, right-click the control and choose **End Template Editing**.
6. Set the appearance of individual templates by setting their style properties.For details, see ASP.NET Server Controls and CSS Styles.

   > **Tip** You can quickly set the appearance of templates by selecting a predefined style scheme. Select the control and then choose **AutoFormat** at the bottom of the Properties window. When you select a scheme, the Designer sets style properties for templates.

Creating Templates Using ASP.NET Syntax

To create a Web server control template using ASP.NET syntax

1. In the .aspx file, insert an element inside the control to identify what template you are creating:

```
<asp:DataList id="DataList1" runat="server">
   <ItemTemplate>
   </ItemTemplate>
</asp:DataList>
```

2. Inside the template element, add HTML text and other controls as the template's content. Include property and data-binding values for the embedded controls using normal syntax:

```
<ItemTemplate>
   Name: <asp:Label runat="server"
          Text="<%# Container.DataListItem.Name %>"/>
</ItemTemplate>
```

3. Repeat Steps 1 and 2 for each template you want to create.

The following example shows a complete declaration for a **DataList** Web server control with simple templates declared for the **Header**, **Item**, and **Separator** templates:

```
<asp:datalist id="DataList1" runat=Server >
   <HeaderTemplate>
      Items matching your query:
   </HeaderTemplate>
   <ItemTemplate>
      Name: <asp:Label id=Label1 runat="server"
      Text='<%# DataBinder.Eval(Container, "DataItem.EmployeeName")
      %>'></asp:Label>
   </ItemTemplate>
   <SeparatorTemplate>
      <br><hr>
   </SeparatorTemplate>
</asp:datalist></p>
```

Note If the Web Forms Designer cannot render a Web server control correctly, it displays a grey box with the text "Error Creating Control." This often means that the ASP.NET syntax of the control is incorrect — for example, if the runat="server"
attribute is missing in a Web server control element, you will see this error. Point to the information icon ( ); a ToolTip is displayed with details about the error.

Web Server Controls Templates | ASP.NET Server Controls | ASP.NET Server Controls and CSS Styles | Creating Web Server Control Templates Dynamically | Creating Templates Programmatically in the DataGrid Control

Creating Web Server Control Templates Dynamically

For various reasons, you might not know until run time what templates you need or what text or controls should be in them. In that case, you need to be able to create the templates dynamically (in code).

> **Note** You can also create templates as Web Forms user controls and bind them dynamically to controls on your page. For details, see Creating a Templated User Control.

You can create templates in code for all controls that use templates: the **DataList**, **Repeater**, and **DataGrid** controls. For the **DataGrid** control, you use templates to define columns instead of the row-like templates for the other two controls.

> **Note** There are a few differences when creating template columns for the **DataGrid** control. For details, see Creating Templates Programmatically in the DataGrid Control.

Creating the Template Class

To create dynamic templates, you create a template class that you can then instantiate when needed.

> **Note** For background on creating classes in Visual Basic .NET, see Understanding Classes. For similar information for Visual C# .NET, see class.

To create a template class

1. Create a new class that implements the **ITemplate** interface of the System.Web.UI namespace.
2. Optionally, pass into the class's constructor a value that the class can use to determine what type of template to create (**ItemTemplate**, **AlternatingItemTemplate**, and so on).

   > **Tip** A type-safe way to pass the template type to the constructor is to add a parameter to the constructor with the type ListItemType. The **ListItemType** enumeration defines the possible template types for the **Repeater**, **DataList**, and **DataGrid** controls.

3. In the class, implement the **InstantiateIn** method (the only member of the **ITemplate** interface). This method provides a way to insert an instance of text and controls into the specified container.
4. In the **InstantiateIn** method, create the controls for the template item, set their properties, and then add them to the parent's **Controls** collection. You can access the parent control via the reference passed to the **InstantiateIn** method.

   > **Note** You cannot directly add static text to the **Controls** collection, but you can create controls like the **Literal** control or the **LiteralControl** control, set their **Text** properties, and then add those controls to the parent collection.

   The following example illustrates a complete template class that displays some static text ("Item number:") and a counter. The counter is maintained as a shared or static value (depending on what language you are using) called `itemcount` for the class and incremented each time a new item is created.

   The class defines an explicit constructor that accepts a **ListItemType** enumeration value to indicate what type of template is being created. Depending on what type of template is being created, the code creates different types of controls and adds them to the **Controls** collection of the parent control. The end result is an HTML table with a different background color for the alternating item template.

```
' Visual Basic
Private Class MyTemplate
   Implements ITemplate
   Shared itemcount As Integer = 0
   Dim TemplateType As ListItemType

   Sub New(ByVal type As ListItemType)
      TemplateType = type
   End Sub

   Sub InstantiateIn(ByVal container As Control) _
      Implements ITemplate.InstantiateIn
      Dim lc As New Literal()
```

```
      Select Case TemplateType
         Case ListItemType.Header
            lc.Text = "<TABLE border=1><TR><TH>Items</TH></TR>"
         Case ListItemType.Item
            lc.Text = "<TR><TD>Item number: " & itemcount.ToString _
               & "</TD></TR>"
         Case ListItemType.AlternatingItem
            lc.Text = "<TR><TD bgcolor=lightblue>Item number: " _
               & itemcount.ToString & "</TD></TR>"
         Case ListItemType.Footer
            lc.Text = "</TABLE>"
      End Select
      container.Controls.Add(lc)
      itemcount += 1
   End Sub
End Class

// C#
public class MyTemplate : ITemplate
{
   static int itemcount = 0;
   ListItemType templateType;

   public MyTemplate(ListItemType type)
   {
      templateType = type;
   }

   public void InstantiateIn(System.Web.UI.Control container)
   {
      Literal lc = new Literal();
      switch( templateType )
      {
         case ListItemType.Header:
            lc.Text = "<TABLE border=1><TR><TH>Items</TH></TR>";
            break;
         case ListItemType.Item:
            lc.Text = "<TR><TD>Item number: " + itemcount.ToString() +
               "</TD></TR>";
            break;
         case ListItemType.AlternatingItem:
            lc.Text = "<TR><TD bgcolor=lightblue>Item number: " +
               itemcount.ToString() + "</TD></TR>";
            break;
         case ListItemType.Footer:
            lc.Text = "</TABLE>";
            break;
      }
      container.Controls.Add(lc);
      itemcount += 1;
   }
}
```

Using the Dynamic Template

When you have a dynamic template available, you can instantiate it in code.

> **Note** To work with a dynamic template as a column in a **DataGrid** control, see Creating Templates Programmatically in the DataGrid Control.

To use a dynamic template

1. Create an instance of your dynamic template, passing it an item type value if appropriate.
2. Assign the instance to one of the template properties of the **Repeater** or **DataList** control: ItemTemplate, AlternatingItemTemplate, HeaderTemplate, and so on.

   The following example shows how to use the dynamic template with a **Repeater** control. In this example, the templates are instantiated while the page is being loaded and before the control is bound to its data source.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   Repeater1.HeaderTemplate = New MyTemplate(ListItemType.Header)
   Repeater1.ItemTemplate = New MyTemplate(ListItemType.Item)
   Repeater1.AlternatingItemTemplate = _
      New MyTemplate(ListItemType.AlternatingItem)
   Repeater1.FooterTemplate = New MyTemplate(ListItemType.Footer)
   SqlDataAdapter1.Fill(DsCategories1)
   Repeater1.DataBind()
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   Repeater1.HeaderTemplate = new MyTemplate(ListItemType.Header);
   Repeater1.ItemTemplate = new MyTemplate(ListItemType.Item);
   Repeater1.AlternatingItemTemplate =
      new MyTemplate(ListItemType.AlternatingItem);
   Repeater1.FooterTemplate = new MyTemplate(ListItemType.Footer);
   sqlDataAdapter1.Fill(dsCategories1);
   Repeater1.DataBind();
}
```

Adding Data Binding to Templates

There are various ways to get access to data from within a template class, depending on how you have created the class. A good way is one in which the page architecture itself implements data binding — when you add controls to the template, you also add a handler for their **DataBinding** event. This event will be raised after the template item has been created with all its controls, and it provides you with an opportunity to fetch data and use it in a control.

> **Note** You cannot embed a data-binding expression as a string when creating controls in the template, as you do when defining templates at design time, because data-binding expressions are converted into code at a stage of page processing that occurs before your template is created.

In the handler for the **DataBinding** event, you have an opportunity to manipulate the contents of the control. Typically (but not necessarily), you fetch data from somewhere and assign it to the control's **Text** property.

> **Note** For background on data binding in Web Forms pages, see Web Forms Data Binding.

To add data binding to a dynamic template, you must do the following:

- Add a data-binding event handler to the controls you create in the template.
- Create the handler that you are binding to. In the handler, get the data that you want to bind to and assign it to the appropriate property of the control being bound.

To add the data-binding event handler

- After creating a control in the dynamic template, use standard commands to bind the control's **DataBinding** event to a method that you will create later.

  > **Note** For details on how to add event handlers dynamically, see AddHandler and RemoveHandler (for Visual Basic) and Events Tutorial (for Visual C#).

The following example shows code from the template class illustrating how you can bind a newly created control to a method called `TemplateControl_DataBinding`.

```
' Visual Basic
Dim lc As New Literal()
   Case ListItemType.Item
   lc.Text = "<TR><TD>"
   AddHandler lc.DataBinding, AddressOf TemplateControl_DataBinding

// C#
Literal lc = new Literal();
case ListItemType.Item:
   lc.Text = "<TR><TD>";
   lc.DataBinding += new EventHandler(TemplateControl_DataBinding);
   break;
```

Note that in this example, the text you add to the literal control's **Text** property is different than in the previous example. It contains only the beginning of the table row and cell for the item template. You will complete the cell and row in the data-binding event handler.

The next step is to create the event handler that will be called when the control is data bound.

To create the handler for the DataBinding event

1. Create a method that is part of your template class as a peer of the class's other methods (such as **InstantiateIn**). The handler's name must match the name you used when binding the event earlier. The method should have the following signature:

```
' Visual Basic
Private Sub TemplateControl_DataBinding(ByVal sender As Object, _
   ByVal e As System.EventArgs)

// C#
private void TemplateControl_DataBinding(object sender,
   System.EventArgs e)
```

2. Get a reference to the **DataItem** object containing the data for the current template item, by doing the following:
   a. Get a reference to the template item. You create a variable to hold the reference and then assign it the value you get from your control's **NamingContainer** property.
   b. Use that reference to get the naming container's (the template item's) **DataItem** property.
   c. Extract the individual data element (data column, for example) from the **DataItem** object and use it to set a property of the control you are binding.

   The following code illustrates one way to perform data binding within a dynamic template. It shows a complete data-binding event handler for **Literal** controls being created in a template for a **Repeater** control.

```
' Visual Basic
Private Sub TemplateControl_DataBinding(ByVal sender As Object, _
   ByVal e As System.EventArgs)
   Dim lc As Literal
   lc = CType(sender, Literal)
   Dim container As RepeaterItem
   container = CType(lc.NamingContainer, RepeaterItem)
   lc.Text &= DataBinder.Eval(container.DataItem, "CategoryName")
   lc.Text &= "</TD></TR>"
End Sub

// C#
private void TemplateControl_DataBinding(object sender,
```

```
System.EventArgs e)
{
   Literal lc;
   lc = (Literal) sender;
   RepeaterItem container = (RepeaterItem) lc.NamingContainer;
   lc.Text += DataBinder.Eval(container.DataItem, "CategoryName");
   lc.Text += "</TD></TR>";
}
```

Note If you have multiple types of controls in your templates, you would need to create a different data-binding event handler for each of the control types.

Web Server Controls Templates | Creating Templates Programmatically in the DataGrid Control

Setting ASP.NET Server Control Properties

Setting a control's properties defines its appearance and behavior. This topic addresses how to set control properties at design time.

Setting Properties in the Web Forms Designer

The Web Forms Designer provides tools for setting control properties.

To set server controls properties in the designer

- In Design view, select the control, and then set properties in the Properties window.
- In HTML view, place the insertion point in the element tag of the control, and then set properties in the Properties window.

Setting Properties using ASP.NET Syntax

Control properties can be set as part of a control's declaration.

To set server controls properties using ASP.NET syntax

1. Switch to HTML view.
2. In the .aspx file, set the attribute of the control declaration corresponding to the property you want.

   The exact attribute you set depends on the control and the property. For information about the properties for a specific control, search for the name of the control class (for example, "Button class (System.Web.UI.WebControls)" in the Help index.

   > **Note** In Web server controls, the property names do not have the same names as HTML attributes; be sure you are using the correct property name.

   The following example sets the **MaxLength** property of an HtmlInputText control:

   ```
   <input id="MyTextBox" type=text runat=server maxlength=20 >
   ```

   The following example sets the **TextMode** property of a **TextBox** control:

   ```
   <asp:textbox text="Hi" runat=Server TextMode=Multiline />
   ```

See Also

Setting Web Server Control Properties Programmatically | Setting HTML Server Control Properties Programmatically | Customizing the Appearance of ASP.NET Server Controls Using Styles

Setting Web Server Control Properties Programmatically

You can set Web server control properties programmatically to change the control's appearance and behavior at run time. Properties for Web server controls are strongly typed, so the exact technique you use to set properties depends on what type of property you are setting. For example, setting a unit property such as width is different from setting a color property. The sections below provide details about setting different types of properties. For information about the properties for a specific control, search for the name of the control class (for example, "Button class (System.Web.UI.WebControls)" in the Help index.

> **Note** You set HTML server control properties slightly differently. For details, see Setting HTML Server Control Properties Programmatically.

Setting Properties Based on Simple Values or Enumerations

If a Web server control property's data type is a primitive — a **String**, **Boolean**, or numeric type — then you can set the property value by simply assigning it to the property. Similarly, if the property's values are defined in an enumeration class, you can simply assign the enumeration to the property.

To set a property value based on simple values

- Assign the value as a literal or variable, as in the following examples:

```
' Visual Basic
Label1.Text = "Hello"
DataGrid1.PageSize = 5

// C#
Label1.Text = "Hello";
DataGrid1.PageSize = 5;
```

To set a property value based on an enumeration

- Assign the value using one of the enumeration values. The framework can resolve the enumeration based on the property's type. The following illustrates setting a property using an enumeration:

```
' Visual Basic
' Uses TextBoxMode enumeration
Me.TextBox1.TextMode = TextBoxMode.SingleLine
' Uses ImageAlign enumeration
Me.Image1.ImageAlign = ImageAlign.Middle

// C#
// Uses TextBoxMode enumeration
this.TextBox1.TextMode = TextBoxMode.SingleLine;
// Uses ImageAlign enumeration
this.Image1.ImageAlign = ImageAlign.Middle;
```

Setting Unit Properties

Width, height, and similar properties are set in units. Units are implemented as objects (the Unit structure), which allows you to specify a value and the measurement unit in various ways.

To set unit-based properties

- Assign a reference to the **Unit** structure to your control. The following examples show variations on how to do this.

```
' Visual Basic
' Default is pixels.
TextBox1.Width = New Unit(100)
TextBox1.Width = New Unit(100, UnitType.Pixel)
TextBox1.Width = New Unit("100px")
' Centimeters.
```

```
TextBox1.Width = New Unit("2cm")
TextBox1.Width = New Unit(10, UnitType.Percentage)
TextBox1.Width = New Unit("10%")

// C#
// Default is pixels.
TextBox1.Width = new Unit(100);
TextBox1.Width = new Unit(100, UnitType.Pixel);
TextBox1.Width = new Unit("100px");
// Centimeters
TextBox1.Width = new Unit("2cm");
TextBox1.Width = new Unit(10, UnitType.Percentage);
TextBox1.Width = new Unit("10%");
```

Setting Color Properties

To set a property to a color (such as the **BackColor** property), you assign a reference to the **Color** object.

To set properties to a color

- Assign a reference to the **Color** structure to your control. To specify the color, call the **Color** object's **FromArgb** method, passing it a numeric value (RGB) or string name of the color. Alternatively, you can assign the color using a static method that references a predefined color name:

```
' Visual Basic
Button1.BackColor = Color.FromName("Red")
' White in RGB.
Button1.BackColor = Color.FromArgb(255, 255, 255)
Button1.BackColor = Color.Red
' HTML 4.0 Color
Button1.BackColor = Color.MediumSeaGreen

// C#
Button1.BackColor = Color.FromName("Red");
// White in RGB.
Button1.BackColor = Color.FromArgb(255, 255, 255);
Button1.BackColor = Color.Red;
// HTML 4.0 color.
Button1.BackColor = Color.MediumSeaGreen;
```

Setting Control Properties in Collections

The properties of some controls are not simple values or objects, but collections. For example, the individual values of a **ListBox** Web server control are implemented as a collection of **ListItem** objects.

To set a complex control property

- Instantiate the item you want to use, and then add it to the control's collection. The following example shows how to add a **ListItem** object to a list box by adding it to the list box's **Items** collection. In the first example, the item is explicitly created before being added. In the second example, items are created and added at the same time.

```
' Visual Basic
Dim li As ListItem = New ListItem("Item 1")
ListBox1.Items.Add(li)

' Create and add the items at the same time
ListBox1.Items.Add(New ListItem("Apples"))
ListBox1.Items.Add(New ListItem("Oranges"))
ListBox1.Items.Add(New ListItem("Lemons"))

// C#
```

```
// Create the items and then add them to the list.
ListItem li = new ListItem("Item 1");
ListBox1.Items.Add(li);

// Create and add the items at the same time.
ListBox1.Items.Add(new ListItem ("Apples"));
ListBox1.Items.Add(new ListItem ("Oranges"));
ListBox1.Items.Add(new ListItem ("Lemons"));
```

Customizing the Appearance of ASP.NET Server Controls Using Styles | Setting HTML Server Control Properties Programmatically | Setting ASP.NET Server Control Properties

Setting HTML Server Control Properties Programmatically

HTML server controls are of two slightly different types. The HTML elements most commonly used in forms are available as individual HTML server controls, such as HtmlInputText, HtmlInputButton, HtmlTable, and so on. These HTML server controls expose their own, control-specific properties that map directly to HTML attributes. However, any HTML element can be converted to a control. In that case, the element becomes an HtmlGenericControl with base class properties such as **TagName**, **Visible**, and **InnerHTML**.

To set properties of HTML server controls

- Get or set the property name as you would with any object. All properties are either strings or integers. The following examples illustrate this:

```
' Visual Basic
myAnchor.Href = "http://www.microsoft.com"
Text1.MaxLength = 20
Text1.Value = string.Format("{0:$###}", TotalCost)
Span1.InnerHTML = "You must enter a value for Email Address."

// C#
myAnchor.HRef = "http://www.microsoft.com";
Text1.MaxLength = 20;
Text1.Value = string.Format("{0:$####}", TotalCost);
Span1.InnerHtml = "You must enter a value for Email Address.";
```

All HTML server controls also support an **Attributes** collection, which gives you direct access to all the control's attributes. This is particularly useful for working with attributes that are not exposed as individual properties.

To work with control attributes directly

- Use the properties and methods of a control's **Attributes** collection, such as **Add**, **Remove**, **Clear**, and **Count**. The **Keys** property returns a collection containing the names of all the attributes in the control. The following examples show various ways to use the **Attributes** collection:

```
' Visual Basic
' Adds new attribute.
Text1.Attributes.Add("bgcolor", "red")
' Removes one attribute.
Text1.Attributes.Remove("maxlength")
' Removes all attributes, clearing all properties.
Text1.Attributes.Clear()
' Creates comma-delimited list of defined attributes
Dim strTemp As String = ""
Dim key As String
For Each key In Text1.Attributes.Keys
   strTemp &= Text1.Attributes(key) & ", "
Next

// C#
// Adds a new attribute.
Text1.Attributes.Add("bgcolor","red");
// Removes one attribute.
Text1.Attributes.Remove("maxlength");
// Removes all attributes, clearing all properties.
Text1.Attributes.Clear();
// Creates comma-delimited list of defined attributes
string strTemp = "";
foreach (string key in Text1.Attributes.Keys)
{
   strTemp += Text1.Attributes[key] + ", ";
```

```
}
```

Specifying Whether Controls Post to the Server

By default, information and selections that the user specifies in a Web Forms page are not posted immediately to the server. Instead, the values are posted only when the entire form is posted, usually in response to clicking a button. However, you might find it useful at times to send user changes to the server immediately.

To post control values to the server immediately

- Set the control's **AutoPostBack** property to **true**.

You can also respond to user actions by creating client scripts. For example, you can create a client script to respond to the **Click** event of a button or check box. For more information, see Client Script in Web Forms Pages.

Web Forms Control Identification

Every control on a Web Forms page must be uniquely identifiable. Generally, you assign a value to a control's **ID** property to uniquely identify it. This value becomes the instance name of the control — that is, the name by which you can refer to the control in code. For example, if you set the ID property of a **TextBox** control to "Text1," then you can reference the control in code as `Text1`.

A number of data-bound controls, including the DataList, Repeater, and DataGrid controls, act as containers for other (child) controls. When these controls run, they generate multiple instances of the child control. For example, if you create a **DataList** template with a **Label** control in it, when the page runs, there are as many instances of that **Label** control in the page as there are records in the **DataList** control's data source.

> **Note** Controls that use templates, such as the **DataList** and **Repeater** controls, host template objects. For example, when the **DataList** control runs, it creates multiple instances of the **DataListItem** class. These template objects in turn contain individual controls such as labels, text boxes, buttons, and so on.

Because controls can be instantiated multiple times on the same page, and because you can reuse control names on different pages, the ASP.NET page framework provides mechanisms to ensure that controls on the page and in your application have unique identifiers. It also provides you with ways to find these individual controls so that you can manipulate them in your own code.

The Naming Container

Controls that can act as containers for other controls generate a *naming container*, or an ID namespace, for their child controls. By providing this naming container, controls can guarantee that ID attributes of their child controls are unique within the entire application. (Controls generate a naming container by implementing the INamingContainer interface.) When child controls are created at run time, the naming container is combined with the child control's ID property to create the value of the UniqueID property of each child control. The **UniqueID** property therefore becomes a fully-qualified identifier for a control, referencing its naming container as well the controls' individual ID value.

In the example from above, the multiple instances of the **Label** control are created within the naming container — the namespace — of the parent **DataList** control. The **UniqueID** property of each **Label** control will reflect this namespace, which will have a format something like `DataList1:_ctl:MyLabel`, `DataList1:_ct2:MyLabel`, and so on.

> **Note** As a rule, you should not write code that references controls using the value of the generated **UniqueID** property. You can treat the **UniqueID** property as a handle (for example, by passing it to a process), but you should not rely on it having a specific structure.

In addition to each container control providing a naming container for its child controls, the page itself also provides a naming container for all of its child controls. This creates a unique namespace within the application for all the controls on that page.

Using the NamingContainer Property

Child controls can reference their naming container via the NamingContainer property. This property returns an object of type Control that you can cast to the appropriate **DataList** control, **DataListItem** object, and so on.

Referencing the naming container is useful when you need access from a child control to a property of the container control. For example, in a handler for a child control's **DataBinding** event, you can access the **DataItem** object by getting it from the naming container.

> **Note** The **NamingContainer** property does not necessarily reference the same control as the **Parent** property. For example, in a **Repeater** control, you might have an item template containing a table that in turn contains a **Label** control. The parent control of the label is a table cell (for example, a **HtmlTableCell** object), but its naming container is the **DataListItem** object, because it is the **DataListItem** that defines the namespace for the **Label** control, not the table.

Referencing Controls

If your page contains controls that are generated at run time, such as those in a template for the **DataList**, **Repeater**, or **DataGrid** controls, you cannot directly reference them by their ID, because the ID is not unique. However, there are various ways to find individual controls in the page. For details, see Referencing Controls in Web Forms Pages.

See Also

Referencing Controls in Web Forms Pages

When you are working with controls in templates, you cannot always directly reference the controls in code. For example, if you add a **Label** control to a **DataList** control and name it "Label1," you cannot get or set its properties at run time by simply referring to `Label1` in code. The page class does not contain an instance of the control that you can use directly, because there are typically multiple instances of the control. For more information, see Web Forms Control Identification.

Similarly, there are times when you are working with a control and need access to properties or methods of its naming container.

The sections below describe various ways in which you can get access to controls when you are working with naming containers and child controls.

Locating a Child Control by ID

You can get a reference to a specific control using a method that searches its naming container by its assigned ID.

To locate a control by ID

- Call the FindControl method of the naming container, passing it a string containing the ID of the control you want to use. The method returns an object of type Control that you can cast to the appropriate type.

  The following example shows how you can locate a specific control. The sample is a handler for the **Click** event of a button in a **DataGrid** control. When the button is clicked, the code searches for a label named `Label1` in the current **DataGrid** item (which is the **Label** control's naming container). If the label is found, its text is displayed in a second label (`LabelText`) elsewhere on the page.

```
' Visual Basic
Private Sub DataGrid1_ItemCommand(ByVal source As Object, _
   ByVal e As System.Web.UI.WebControls.DataGridCommandEventArgs) _
   Handles DataGrid1.ItemCommand
   Dim l As Label
   l = CType(e.Item.FindControl("Label1"), Label)
   If (Not l Is Nothing) Then
      LabelText.Text = l.Text
   End If
End Sub

// C#
private void DataGrid1_ItemCommand(object source,
   System.Web.UI.WebControls.DataGridCommandEventArgs e)
{
   Label l;
   l = (Label) e.Item.FindControl("Label1");

   if(!(l == null) ){
      LabelText.Text = l.Text;
   }
}
```

Accessing Members of the Naming Container

At times, you need to access properties or methods of a control's naming container. For example, during data binding, the container control makes available a **DataItem** property containing the data to which controls are bound. You can access the containing control in different ways, depending on context.

In Declarative Data-Binding Expressions

In data-binding expressions, you can access the container control using the special keyword `Container`. (For information on these expressions, see Data-Binding Expressions for Web Forms Pages.)

To access the naming container from a data-binding expression

- In the data-binding expression, use the **Container** keyword, which returns a reference to the container. You can then access the container's properties or methods.

  This keyword is used most commonly in the **DataBinder.Eval** method to get values from the naming container's **DataItem** object, but can be used outside of that method as well. The following example shows a **Label** control that might be in a template for a **DataList**, **Repeater**, or **DataGrid** control. It displays the current item number.

```
<asp:Label id=Label1 runat="server"
   Text='<%# Container.ItemIndex + 1  %>'>
</asp:Label>
```

  The following example is similar, but gets a value from the naming container's **DataItem** object:

```
<asp:Label id=Label1 runat="server"
   Text='<%# Container.DataItem("title") %>'>
</asp:Label>
```

In Code

In the code for a page, you can access a control's naming container by getting its **NamingContainer** property.

> **Note** The **NamingContainer** property does not necessarily reference the same control as the **Parent** property. For example, in a **Repeater** control, you might have an item template containing a table that in turn contains a **Label** control. The parent control of the label is a table cell (for example, a **HtmlTableCell** object), but its naming container is the **DataListItem** object, because it is the **DataListItem** that defines the namespace for the **Label** control, not the table.

To access the naming container from code

- Get the control's **NamingContainer** property and cast it to the container's class type, such as DataGridItem.

  For an example of using the **NamingContainer** property to get information about an individual control's naming container, see the section "Selecting Multiple Items Using a Check Box (Hotmail Model)" in the article Top Questions about the DataGrid Web Server Control.

Locating a Control by Walking the Controls Collection

Every container control on the page, and the page itself, has a **Controls** collection that you can use to get to individual controls.

To locate controls in the Controls collection

- Loop through the **Controls** collection of the container control. The collection is of type ControlCollection, and returns objects of type Control.

  The following example illustrates how to walk the **Controls** collection. The example assumes a Web Forms page with at least one **Textbox** control on it, a **Label** control, and a button. The code gets all the child controls of the **Page** object. Because this would produce only a few high-level child controls, including the **HtmlForm** object, the code also walks the **Controls** collection of each individual child control. The code looks for text boxes by comparing the type of each control. When it finds a text box, it gets that control's value and concatenates it into a string that is displayed at the end in a **Label** control.

  This example finds only the controls contained in the **Page** object and the controls that are direct children of the page. It does not find text boxes that are children of a control that is in turn a child of the page. For example, if you dragged a **Panel** control on the designer, the **Panel** control would be a child of the **HtmlForm** control contained by the **Page**, and it would be found in this example. However, if you then dragged a **TextBox** control onto the **Panel** control, the **TextBox** control text would not be displayed by the example, because it is not a child of the page or of a control that is a child of the page. A more practical application of walking the controls this way would be to create a recursive method that can be called to walk the **Controls** collection of each control as it is encountered. However, for clarity, the example below is not created as a recursive function.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, _
```

```
    ByVal e As System.EventArgs) Handles Button1.Click
    Dim allTextBoxValues As String = ""
    Dim c As Control
    Dim childc As Control
    For Each c In Page.Controls
       For Each childc In c.Controls
          If TypeOf childc Is TextBox Then
             allTextBoxValues &= CType(childc, TextBox).Text & ","
          End If
       Next
    Next
    If allTextBoxValues <> "" Then
       Label1.Text = allTextBoxValues
    End If
End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e)
{
   string allTextBoxValues = "";
   foreach (Control c in Page.Controls)
   {
      foreach (Control childc in c.Controls)
      {
         if (childc is TextBox)
         {
            allTextBoxValues += ((TextBox)childc).Text + ",";
         }
      }
   }
   if(allTextBoxValues != "")
   {
      Label1.Text = allTextBoxValues;
   }
}
```

Web Forms Validation

An important aspect of creating Web Forms pages for user input is to be able to check that the information users enter is valid. ASP.NET provides a set of validation controls that provide an easy-to-use but powerful way to check for errors and, if necessary, display messages to the user.

The following topics tell you more about validation controls and how to use them.

In This Section

Introduction to Validating User Input in Web Forms
Provides background information about using validation controls.
Types of Validation for ASP.NET Server Controls
Lists which validation controls are available and what types of validation you can perform with them.
Client-Side Validation for ASP.NET Server Controls
Explains how validation works in browsers that support Dynamic HTML (such as Internet Explorer 4.0 or later).
Special-Case Validation Results for ASP.NET Server Controls
Describes how validation controls work under specific circumstances and how they interact with one another.
Validation Error Message Layout for ASP.NET Server Controls
Describes how error message display affects the layout of your page.
Validating Required Entries for ASP.NET Server Controls
Gives directions for making sure users do not skip a field.
Validating Against a Specific Value for ASP.NET Server Controls
Gives directions for making sure users enter only one of a restricted set of values.
Validating Against a Data Type for ASP.NET Server Controls
Gives directions for making sure users enter only a date, a number, or some other specific data format.
Validating Against Patterns for ASP.NET Server Controls
Gives directions for checking that a user's entry follows a specific sequence of numbers, letters, or other characters (such as a phone number, postal code, e-mail address, and so on).
Validating Against a Range of Values for ASP.NET Server Controls
Gives directions for checking that a user's entry falls between a specified low and high value.
Validating Against Values in a Database for ASP.NET Server Controls
Gives directions for checking if a user's entry is contained in a table of acceptable or correct values.
Validating with a Custom Function for ASP.NET Server Controls
Gives directions for creating your own validation logic and tying it to a validation control.
Testing Validity Programmatically for ASP.NET Server Controls
Gives directions for testing whether the user's entries passed validation checking.
Controlling Validation Error Message Display for ASP.NET Server Controls
Gives directions for specifying where error messages are displayed.
Formatting Validation Error Messages for ASP.NET Server Controls
Gives directions for setting font, color, and other attributes of error messages.
Specifying Layout for In-Place Messages On ASP.NET Server Controls
Gives directions for controlling page layout with error-message display.
Disabling Validation for ASP.NET Server Controls
Gives directions for turning off validation in code.
Displaying Custom Error Messages for ASP.NET Server Controls
Gives directions for creating your own error display.
Validating Programmatically for ASP.NET Server Controls
Gives directions for calling validation controls from your own code.

Walkthrough: Validating User Input in a Web Forms Page

Describes how to use Web Forms validation controls to check user entries without code, including required entries, data types, ranges, patterns, and specific values.

Introduction to Validating User Input in Web Forms

You can add input validation to Web Forms pages by using validation controls. Validation controls provide an easy-to-use mechanism for all common types of standard validation — for example, testing for valid dates or values within a range — plus ways to provide custom-written validation. In addition, validation controls allow you to completely customize how error information is displayed to the user.

Validation controls can be used with any controls that are processed in a Web Forms page's class file, including both HTML and Web server controls. For more information, see Introduction to ASP.NET Server Controls.

> **Security Note** By default, the Web Forms page automatically validates that malicious users are not attempting to send script to your application. For more information, see Scripting Exploits.

Using Validation Controls

You enable validation of user input by adding validation controls to your form as you would other server controls. There are controls for different types of validation, such as range checking or pattern matching. A complete list appears in the topic Types of Validation for ASP.NET Server Controls.

Each validation control references an input control (a server control) elsewhere on the page. When the user's input is being processed (for example, when the form is submitted), the ASP.NET page framework passes the user's entry to the appropriate validation control or controls. The validation controls test the user's input and set a property to indicate whether the entry passed the test. After all validation controls have been called, a property on the page is set; if any of the controls shows that a validation check failed, the entire page is set to invalid.

You can test the state of the page and of individual controls in your own code. For example, you would test the state of the validation controls before updating a data record with information entered by the user. If you detect an invalid state, you bypass the update. Typically, if any validation checks fail, you skip all your own processing and return the page to the user. Validation controls that detect errors then produce an error message that appears on the page.

When Validation Occurs

Validation occurs after page initialization (that is, after view-state and postback data have been processed) but before Change or Click event handlers are called.

You can perform the validation procedure earlier by calling the control's **Validate** method, for example during page load. For more details, see Validating Programmatically for ASP.NET Server Controls.

Validating for Multiple Conditions

Generally speaking, each validation control performs just one test. However, frequently you want to check for multiple conditions. For example, you might want to establish that a field is required and that it is limited to accepting dates within a specific range.

You can attach more than one validation control to an input field on a form. In that case, the tests performed by the controls are resolved using a logical AND. The data input by the user must pass all the tests in order to be considered valid.

In some instances, entries in several different formats might be valid. For example, if you are prompting for a phone number, you might allow users to enter a local number, a long-distance number, or an international number. This situation arises primarily when checking for specific patterns of numbers or characters. To perform this type of test — a logical OR — you use the pattern-matching validation control and specify multiple valid patterns within the control. Using multiple validation controls would not work in this instance because they are tested with a logical AND.

Displaying Error Information

Validation controls are normally not visible in the rendered form. However, if the control detects an error, it produces error message text that you specify. The error message can be displayed in a variety of ways, as listed in the following table.

Display option	Description
In place	Each validation control can individually display an error message or glyph in place (usually next to the control where the error occurred).
Summary	Validation errors can be collected and displayed in one place — for example, at the top of the page. This strategy is often used in combination with displaying a glyph next to the input fields with errors. If the user is working in Internet Explorer 4.0 or later, the summary can be displayed in a message box.

In place and Summary	The error message can be different in the summary and in place. You can use this option to show a shorter error message in place with more detail in the summary, or to show an error glyph next to the input field and an error message in the summary.
Custom	You can create custom error display by capturing the error information and designing your own output.

If you use the in-place or summary display options, you can format the error message text using HTML.

> **Security Note** If you create custom error messages, be sure you do not display information that might help a malicious user compromise your application. For details, see Displaying Safe Error Messages.

Server-Side and Client-Side Validation

Validation controls perform input checking in server code. When the user submits a form to the server, the validation controls are invoked to review the user's input, control by control. If an error has occurred in any of the input controls, the page itself is set to an invalid state so you can test for validity before your code runs.

If the user is working with a browser that supports DHTML, the validation controls can also perform validation using client script. This can substantially improve response time in the page; errors are detected immediately and error messages are displayed as soon as the user leaves the control containing the error. If client-side validation is available, you have greater control over the layout of error messages and can display an error summary in a message box. For more details, see Client-Side Validation for ASP.NET Server Controls.

The page framework performs validation on the server even if the validation controls have already performed it on the client, so that you can test for validity within your server-based event handlers. In addition, it helps prevent users from being able to bypass validation by disabling or changing the client script.

Validation Object Model

You can interact with validation controls using the object model exposed by individual validation controls and by the page. Each validation control exposes its own **IsValid** property that you can test to see if a validation test has passed or failed for that control.

At the page level you have access to another **IsValid** page property that summarizes the **IsValid** state of all the validation controls on the page. This property makes it easy to do a quick test to see if you can safely proceed with your own processing.

The page also exposes a **Validators** collection containing a list of all the validation controls on the page. You can loop through this collection to examine the state of individual validation controls.

> **Note** There are a few differences in the object model for client-side validation. For details, see Client-Side Validation for ASP.NET Server Controls.

Custom Validation

You can customize the validation process in a number of ways:

- You have complete control over the format, text, and location of error messages, and you can specify whether they appear individually or in summary form.
- You can create custom validation using a special control. The control calls your logic but otherwise works the same as other validation controls in setting error state, displaying error messages, and so on. This provides an easy way to create custom validation logic but still participate in the validation framework of the page.
- If you have specified client-side validation, you can intercept the validation call and substitute or add your own validation logic.

Validating Programmatically

By default, validation controls perform their checks when the Click events are processed. However, you can perform validation at any time in your code by calling a validation control's **Validate** method. Calling this method allows you to evaluate the validity of property settings made programmatically. For example, you might gather data from a user by a method other than a Web Forms page, and then set properties of server controls programmatically.

For more details, see Validating Programmatically for ASP.NET Server Controls.

Web Forms Validation | Walkthrough: Validating User Input in a Web Forms Page

Types of Validation for ASP.NET Server Controls

The following table lists the types of validation controls available and how you can use them.

> **Security Note** By default, the Web Forms page automatically validates that malicious users are not attempting to send script to your application. For more information, see Scripting Exploits.

Type of validation	Control to use	Description
Required entry	**RequiredFieldValidator**	Ensures that the user does not skip an entry.
Comparison to a value	**CompareValidator**	Compares a user's entry against a constant value, or against a property value of another control, using a comparison operator (less than, equal, greater than, and so on).
Range checking	**RangeValidator**	Checks that a user's entry is between specified lower and upper boundaries. You can check ranges within pairs of numbers, alphabetic characters, and dates.
Pattern matching	**RegularExpressionValidator**	Checks that the entry matches a pattern defined by a regular expression. This type of validation allows you to check for predictable sequences of characters, such as those in social security numbers, e-mail addresses, telephone numbers, postal codes, and so on.
User-defined	**CustomValidator**	Checks the user's entry using validation logic that you write yourself. This type of validation allows you to check for values derived at run time.

You can attach more than one validation control to an input control. For example, you might specify that a control is required, and that it contain a specific range of values.

A related control, the ValidationSummary control, does not perform validation, but it is often used in conjunction with the controls listed above. The purpose of the ValidationSummary control is to display the error messages from all the validation controls on the page together, in a single location. For more information, see Controlling Validation Error Message Display for ASP.NET Server Controls.

Web Forms Validation | Introduction to Validating User Input in Web Forms

Client-Side Validation for ASP.NET Server Controls

If the user is working with Internet Explorer 4.0 or later, validation controls can perform validation using client script. Because the controls can provide immediate feedback (without a round trip to the server), the user experience with the page is enhanced.

Under most circumstances, you do not have to make any changes to your page or to the validation controls to use client-side validation. The controls automatically detect if the browser supports DHTML and perform their checking accordingly. Client-side validation uses the same error display mechanism as server-side checking.

> **Security Note** Validation is performed on the server even if it was already performed on the client. This allows you to check validation status in server code and provides security against users bypassing validation.

Differences in Client-Side Validation

There are some additional features of validation available if it is performed on the client:

- If you are summarizing validation error messages, you can display them in a message box that appears when the user submits the page. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.
- The object model for validation controls is slightly different on the client. See "Client Validation Object Model" below.

There are a few minor differences associated with client-side validation:

- If client-side validation is enabled, the page includes references to script libraries that are used to perform the client-side validation.
- When you use a **RegularExpressionValidator** control, the expressions can be checked on the client if an ECMAScript-compatible language (such as Microsoft JScript) is available. This differs in some very small details from the regular expression checking done on the server using the System.Text.RegularExpressions.Regex class.
- The page includes a client-side method to intercept and handle the **OnClick** event before the page is submitted.

Client Validation Object Model

Validation controls present almost the same object model on the client as on the server. For example, you can test validation by reading the value of a validation control's **IsValid** property the same way on both the client and the server.

However, there are differences in the validation information exposed at the page level. On the server, the page supports properties; on the client, it contains global variables. The following table compares the information exposed on the page.

Client Page Variable	Server Page Property
Page_IsValid	**IsValid**
Page_Validators (array) Contains references to all validation controls on the page.	**Validators** (collection) Contains references to all validation controls.
Page_ValidationActive A Boolean value that indicates whether validation should take place. Set this variable to **False** to turn off client-side validation programmatically.	(no equivalent)

> **Note** All page-related validation information should be considered read-only.

Posting with Client-Side Validation Errors

Client-side validation is enabled automatically if you are using Microsoft Internet Explorer 4.0 or later. In some instances, however, you might prefer to use only server-side validation, even if client-side validation is available. For example, client-side validation might not be possible if the validation requires information or resources that are only available on the server, such as access to a database.

By default, when client-side validation is being performed, the user cannot post the form to the server if there are errors on the page. However, you might find it necessary to allow the user to post even with errors. For example, you may have a "Cancel" button or a navigation button on a page, and you want the button to submit the page even if some controls would fail validation. For more information, see Disabling Validation for ASP.NET Server Controls.

> **Note** Client-side validation requires that your browser support ECMAScript 1.2 (JScript) or later, and a Document Object Model (DOM) compatible with Internet Explorer 4.0 or later.

See Also

Special-Case Validation Results for ASP.NET Server Controls

Validation ensures that what the user has entered meets criteria that you specify. In most cases, this is a straightforward operation. However, at times the situations under which input is validated introduce special conditions. It is important that you understand what those conditions are, how validation is performed, and what the results of a validation attempt can be.

Comparing Against Blank Fields

All validation controls except the **RequiredFieldValidator** control consider a field valid if it is blank. You must use the **RequiredFieldValidator** control to prevent a user from leaving a field blank. For example, if you attach a **RangeValidator** control to a date field, validation passes if the user enters a date in the specified range, or if the field is left blank. If you want to ensure that the user enters a date, you must add a **RequiredFieldValidator** control to the date field along with the range check.

Comparing Against Another Control

When using the **CompareValidator** control, you can specify that validation be performed against the value of another control. For example, you might have two fields for entering dates, a start date and an end date. Using a **CompareValidator** control, you can ensure that the start date is less than or equal to the end date.

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

If the validation controls are unable to resolve the value in the other control, they do not raise an error; instead, the validation check passes. This occurs if the value in the other control is missing or cannot be converted to the data type of the **CompareValidator** control.

The specific tests performed by these controls, and possible results, are:

- If the target control entered in the originating control's **ControlToValidate** property does not have a value, **IsValid** = **true** and validation passes.
- If the value of the target control in the **ControlToValidate** property cannot be converted to the appropriate data type, **IsValid** = **false**.
- If the value of the target control in the **ControlToCompare** property cannot be converted to the appropriate data type, then **IsValid** = **true**.
- Finally, if all of these tests have passed, then both controls are non-empty and can be converted to the data type, so the control performs the actual comparison and sets **IsValid** appropriately.

This strategy prevents multiple errors from being reported for the same invalid entry. Validation controls are designed to test and report on only one value and to be able to display as precise a message as possible when an error is encountered.

For example, in the example of the end date, imagine that the user enters an invalid start date. The user then enters an end date. When the validation check is performed (usually on the server), the same bad date could potentially raise an error both for the start date field and for the end date. To prevent this from occurring, the end-date validation — the validation dependent on another field — does not raise an error.

You should therefore ensure that you provide sufficient validation for each individual field. In the example, it would be up to you to make sure that the user has entered a proper date in the start date field. In many cases, you should include a **RequiredFieldValidator** control in addition to a validation control that tests the contents of a specific entry. It is also useful in some cases to add a **CompareValidator** control with **Operator**=**DataTypeCheck**, which does a simple type check without doing a comparison to another value or control.

Validation Error Message Layout for ASP.NET Server Controls

When an error message appears on the page, it becomes part of the layout of the page. You need to design the layout of your page to accommodate error text that might appear.

If validation is being performed on the server, validation controls are not rendered to the page unless an error occurs and therefore take up no space whatsoever. If an error has occurred, the page is recreated during the round trip and the error text is added to the page.

If the user is using a DHTML-compatible browser, validation occurs dynamically on the client. In that case, in-place error message text appears immediately and can potentially change the layout of the page.

To control how error message text is displayed with client validation, you can set the Display property of validation controls to one of three options:

Layout Option	**Description**
Static layout	Each validation control takes up space even when no error message text is visible, allowing you to define a fixed layout for the page. Validation controls cannot occupy the same space on the page, so you must give them each separate locations on the page. This setting only works in Internet Explorer 4.0 or later; in other browsers the layout effectively becomes Dynamic.
Dynamic layout	Validation controls take up no space unless they are displaying an error message, which allows them to share the same location (a table cell, for example). However, when the error message is displayed, the layout of the page changes, sometimes causing controls to change positions.
None	The validation control does not appear on the page.

> **Note** Dynamic layout requires Internet Explorer 4.0 or later. If your Web application will be used with other browsers, it is advisable instead to lay out the validation controls in a table cell or a panel control that is large enough to accommodate the longest possible error message. (For more information see Panel Web Server Control.)

Web Forms Validation | Specifying Layout for In-Place Messages On ASP.NET Server Controls

Validating Required Entries for ASP.NET Server Controls

You can specify that a user must provide information in a specific control by adding a **RequiredFieldValidator** control to the page and linking it to the required control. For example, you can specify that users must fill in a Name field before they can submit a registration form.

If validation is being performed on the client, the user can leave a required field blank while working in the page, but must fill it in before submitting. However, once a value has been entered in the field, the user cannot clear the field. If the field is cleared, the user sees an error message immediately when leaving the field. In server-side validation, no checking is done until the form is submitted, so the user will not see an error message until after the form is submitted.

> **Tip** Required-entry validation is frequently used in conjunction with other types of validation. You can use as many validation controls for a user-entry field as needed.

To validate a required entry

1. Add a **RequiredFieldValidator** control to the page and set the following properties:

Property	Description
ControlToValidate	The ID of the control for which the user must provide a value.
ErrorMessage, **Text**, **Display**	Properties that specify the text and location of the error or errors that will appear if the user skips the control. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

2. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

The following example shows the .aspx file of a Web Forms **TextBox** control with required field validation.

```
<asp:Textbox id="txtLastName" runat="server"></asp:Textbox>
<asp:RequiredFieldValidator id="RequiredFieldValidator1" runat="server"
   ControlToValidate="txtLastName"
   ErrorMessage="Last name is a required field."
   ForeColor="Red">
</asp:RequiredFieldValidator>
```

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls

Validating Against a Specific Value for ASP.NET Server Controls

You can validate a user's entry against a specific single value using logical operators. For example, you can specify that the user's entry is a date after January 1, 1950 or that it is an integer value greater than or equal to zero. Alternatively, you can specify that the user's entry be compared against a value from another control.

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

To validate against a specific value

1. Add a **CompareValidator** control to the page and set the following properties:

Property	Description
ControlToValidate	The ID of the control to validate.
ErrorMessage, **Text**, **Display**	Properties that specify the text and location of the error or errors that will appear if the validation fails. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

2. Set the value to compare to by setting the following properties:

Property	Description
ValueToCompare - or - **ControlToCompare**	An expression entered as a string. To compare to a constant value, set the **ValueToCompare** property. To compare against the value of another control, set the **ControlToCompare** property to the ID of that control (the **CompareValidator** control compares the user's entry against whatever property is specified by the other control's ValidationPropertyAttribute). If you set both **ValueToCompare** and **ControlToCompare**, **ControlToCompare** takes precedence.
Type	The data type of the two values to be compared. Types are specified using the **ValidationDataType** enumeration, which allows you to use the type name **String**, **Integer**, **Double**, **Date**, or **Currency**. The values are converted to this type before the comparison is performed.
Operator	The comparison to use. Operators are specified using the **ValidationCompareOperator** enumeration, which allows you to enter the name of the comparison operators, such as **Equal**, **NotEqual**, **GreaterThan**, **GreaterThanEqual**, and so on.

> **Note** When validation is done against another control, invalid values in the other control are ignored and the validation passes. For details, see Special-Case Validation Results for ASP.NET Server Controls.

3. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

The following example shows the .aspx file of a Web Forms **Textbox** control with a **CompareValidator** control. A table is used to handle layout.

```
<TABLE>
<TR>
<TD>
   <asp:Textbox id="txtAge" runat="server"></asp:Textbox>
</TD>
<TD>
   <asp:CompareValidator id="CompareFieldValidator1" runat="server"
      ForeColor="Red"
      ControlToValidate="txtAge"
      ValueToCompare=0
      Type="Integer"
```

```
        Operator="GreaterThanEqual"
        ErrorMessage="Please enter a whole number zero or greater.">
    </asp:CompareValidator >
</TD>
</TR>
</TABLE>
```

The following example shows a **CompareValidator** that compares the user's entry against the value in another control. In a form that allows users to make reservations at a hotel, the validator checks that the user does not enter a departure date earlier than the arrival date. (In a real application, the departure date would be required and validated as a date as well.)

```
<TABLE>
<TR>
<TD>
   Arrive<asp:Textbox id=txtArrivalDate runat="server"></asp:Textbox>
   Depart<asp:Textbox id=txtDepartureDate runat="server"></asp:Textbox>
</TD>
<TD>
   <asp:CompareValidator id="CompareFieldValidator1" runat="server"
         ForeColor="Red"
         ControlToValidate="txtDepartureDate"
         ControlToCompare="txtArrivalDate"
         Type="Date"
         Operator="GreaterThanEqual"
         ErrorMessage="Departure date cannot be earlier than arrival date.">
   </asp:CompareValidator >
</TD>
</TR>
</TABLE>
```

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls | Validating Required Entries for ASP.NET Server Controls | Validating Against a Data Type for ASP.NET Server Controls

Validating Against a Data Type for ASP.NET Server Controls

You can validate a user's entry against a specific data type to be sure that what the user has entered is a number, or a date, and so on. For example, if you want to collect birth date information on a user registration page, you can use a **CompareValidator** control to make sure that the date is in a recognized format before it is submitted to your database.

To validate against a data type

1. Add a **CompareValidator** control to the page and set the following properties:

Property	Description
ControlToValidate	The ID of the control for which you are checking the data type.
ErrorMessage, **Text**, **Display**	Properties that specify the text and location of the error or errors that will display if the validation fails. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

2. Set the data type to compare to by setting the following properties:

Property	Description
Type	The data type to check against. The type is specified using the **ValidationDataType** enumeration, which allows you to use the type names **String**, **Integer**, **Double**, **Date**, or **Currency**.
Operator	**DataTypeCheck**.

   Note If the user leaves a control blank, the control passes the comparison validation. To force the user to enter a value, add a **RequiredFieldValidator** control as well. For details, see Validating Required Entries for ASP.NET Server Controls.

3. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls

Validating Against Patterns for ASP.NET Server Controls

You can check that a user's entry matches a predefined pattern, such as a phone number, postal code, e-mail address, and so on. To do so, you use a regular expression. For more information on regular expressions, see .NET Framework Regular Expressions.

> **Security Note** By default, the Web Forms page automatically validates that malicious users are not attempting to send script or HTML elements to your application. As long as this validation is enabled, you do not need to explicitly check for script or HTML elements in user input. For more information, see Scripting Exploits.

To validate against a regular expression

1. Add a **RegularExpressionValidator** control to the page and set the following properties:

Property	Description
ControlToValidate	The ID of the control you are validating.
ErrorMessage, **Text**, **Display**	Properties that specify the text and location of the error or errors that will display if the validation fails. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

2. Set the pattern to compare to by setting the **ValidationExpression** property to a regular expression. To select from predefined patterns, click the **ValidationExpression** property in the Properties window and then click the ellipsis button (...).

   If you want to allow multiple valid patterns, use the bar character (|) to separate expressions.

   > **Note** In client-side validation, regular expressions are evaluated using ECMAScript (JScript). This differs in minor ways from server-side regular-expression checking.

3. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

   The following example shows how you can use a **RegularExpressionValidator** control to check whether users enter a valid United States ZIP code. The validator checks for two patterns: five digits, and five digits plus a hyphen plus four more digits.

```
ZIP: <asp:TextBox id=txtZIP runat="SERVER"></asp:TextBox>
<asp:RegularExpressionValidator
     id=txtZIP_validation runat="SERVER"
     ControlToValidate="txtZIP"
     ErrorMessage="Enter a valid US ZIP code."
     ValidationExpression="\d{5}(-\d{4})?">
</asp:RegularExpressionValidator>
```

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls

Validating Against a Range of Values for ASP.NET Server Controls

You can check that a user's entry falls within a specific range of values — for example, between two numbers, between two dates, or between alphabetic characters. You set the upper and lower bounds of the range as properties of a **RangeValidator** control.

You must also specify the data type of the values that the control will validate. If the user's entry cannot be converted to the specified data type — for example, it cannot be converted to a date — the validation fails.

To validate against a range of values

1. Add a **RangeValidator** control to the page and set the following properties:

Property	Description
ControlToValidate	The ID of the control you are validating.
ErrorMessage, **Text**, **Display**	Properties that specify the text and location of the error or errors that will display if the validation fails. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

2. Set the low and high values of the range using the **MinimumValue** and **MaximumValue** properties.
3. Set the **Type** property to specify the data type of the range settings. Use the **ValidationDataType** enumeration, which allows you to use the type name **String**, **Integer**, **Double**, **Date**, or **Currency**.

   > **Note** If the user leaves a control blank, the control passes the range validation. To force the user to enter a value, add a **RequiredFieldValidator** control as well. For details, see Validating Required Entries for ASP.NET Server Controls.

4. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls

Validating Against Values in a Database for ASP.NET Server Controls

You can validate a user's entry against a database to be sure that what the user has entered is a recognized value. To do this, you must write code in a CustomValidator control that loops through a table and looks for data matches.

To validate against a database

1. Add a **CustomValidator** control to the page and set the following properties:

Property	Description
ControlToValidate	The ID of the control that you want to validate.
ErrorMessage, **Text**, **Display**	Properties that specify the text and location of the error or errors that will display if the validation fails. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

2. Create an event handler for the CustomValidator control's ServerValidate event. In the event handler, add code to look through the database and check the user's input against the dataset.

   Note If the user leaves a control blank, the control passes the comparison validation. To force the user to enter a value, add a **RequiredFieldValidator** control as well. For details, see Validating Required Entries for ASP.NET Server Controls.

3. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

The following example shows how you can validate a user's entry by looking it up in a table. In this instance, the user has entered an e-mail address that is validated against e-mail addresses stored in a table. The custom validation logic loops through the rows in a table that is part of the dataset available to the page.

```
' Visual Basic
Private Sub CustomValidator1_ServerValidate(ByVal _
   source As System.Object, ByVal args As _
   System.Web.UI.WebControls.ServerValidateEventArgs) _
   Handles CustomValidator1.ServerValidate
   Dim dv As DataView
   dv = dataset11.Tables(0).DefaultView
   Dim datarow As DataRowView
   Dim txtEmail As String
   args.IsValid = False    ' Assume False
   ' Loop through table and compare each record against user's entry
   For Each datarow In dv
      ' Extract e-mail address from the current row
      txtEmail = datarow.Item("Alias").ToString()
      ' Compare e-mail address against user's entry
      If txtEmail = args.Value Then
         args.IsValid = True
         Exit For
      End If
   Next
End Sub

// C#
private void CustomValidator1_ServerValidate(object source, System.Web.UI.WebControls.ServerV
alidateEventArgs args)
{
   DataView dv;
   dv = dataSet11.Tables[0].DefaultView;
   string txtEmail;
   args.IsValid = false;    // Assume False
   // Loop through table and compare each record against user's entry
   foreach(DataRowView datarow in dv)
   {
      // Extract e-mail address from the current row
      txtEmail = datarow["Alias "].ToString();
```

```
        // Compare e-mail address against user's entry
        if (txtEmail == args.Value)
        {
           args.IsValid = true;
        }
    }
}
```

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls

Validating with a Custom Function for ASP.NET Server Controls

If the existing validation controls do not suit your needs, you can define a custom server-side validation function and call it using the **CustomValidator** control. You can also add client-side validation for a quick check before the form is submitted by writing a function in ECMAScript (JScript) that duplicates the logic of the server-side method.

You should perform a server-side validation even if you use a client-side check. Server-side validation helps prevent users from bypassing validation by disabling or changing the client script.

> **Security Note** By default, the Web Forms page automatically validates that malicious users are not attempting to send script or HTML elements to your application. As long as this validation is enabled, you do not need to explicitly check for script or HTML elements in user input. For more information, see Scripting Exploits.

Server-Side Validation

You define server-side validation by writing code in the control's ServerValidate event handler that checks the user's input. You hook up the event handler by setting the OnServerValidate attribute of the control. The string from the input control to validate can be accessed by using the **Value** property of the **ServerValidateEventArgs** object passed into the event handler as a parameter. The result of the validation is then stored in the **IsValid** property of the **ServerValidateEventArgs** object.

To validate on the server using a custom function

1. Add a **CustomValidator** control to the page and set the following properties:

Property	Description
ControlToValidate	The ID of the control you are validating.
ErrorMessage, **Text**, **Display**	Properties that specify the text and location of the error or errors that will display if the validation fails. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

2. Create a server-based event handler for the control's **ServerValidate** event. This event is called to perform the validation. The method has a signature such as the following:

```
Protected Sub CustomValidator1_ServerValidate(ByVal _
   source As System.Object, ByVal args As _
   System.Web.UI.WebControls.ServerValidateEventArgs) _
   Handles CustomValidator1.ServerValidate

// C#
protected void ValidationFunctionName(object source, ServerValidateEventArgs args)
```

   The source parameter is a reference to the custom validation control raising this event. The property **args.Value** will contain the user input to validate, and **args.IsValid** should be set to **true** if the value is valid, **false** otherwise.

   The following example shows how you can create custom validation. The event handler checks whether the user's entry is eight characters long or longer.

```
' Visual Basic
Protected Sub TextValidate(ByVal source As System.Object, _
   ByVal args As System.Web.UI.WebControls.ServerValidateEventArgs) _
   Handles CustomValidator1.ServerValidate
   args.IsValid = (args.Value.Length >= 8)
End Sub

// C#
protected void TextValidate(object source, ServerValidateEventArgs args)
{
   args.IsValid = (args.Value.Length >= 8);
}
```

3. Add the **OnServerValidate** attribute to the validator in HTML view to indicate the name of the validation function.

```
<asp:textbox id=TextBox1 runat="server"></asp:textbox>
<asp:CustomValidator id="CustomValidator1" runat="server"
   OnServerValidate="TextValidate"
   ControlToValidate="TextBox1"
   ErrorMessage="Text must be 8 or more characters.">
</asp:CustomValidator>
```

4. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

Client-Side Validation

You can also create client-side custom validation. To do so, you specify a function name for the control's ClientValidationFunction property, and create a function in client script that duplicates the logic of the server-side method.

To create custom validation logic on the client

1. Create a validation function on the client side in ECMAScript (JavaScript, JScript).

   The following example illustrates custom client-side validation. An excerpt from the page shows a **Textbox** control referenced by a **CustomValidator** control. The validation control calls a function called `validateLength` to make sure that the user has entered at least eight characters into the **Textbox** control.

```
<SCRIPT LANGUAGE="JavaScript">
function validateLength(oSrc, args){
   args.IsValid = (args.Value.length >= 8);
}
</SCRIPT>

<asp:Textbox id="text1" runat="server" text="">
</asp:Textbox>

<asp:CustomValidator id="CustomValidator1" runat=server
      ControlToValidate = "text1"
      ErrorMessage = "You must enter at least 8 characters!"
   ClientValidationFunction="validateLength" >
</asp:CustomValidator>
```

2. Add a test in your Web Forms code to check for validity. For details, see Testing Validity Programmatically for ASP.NET Server Controls.

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls

Testing Validity Programmatically for ASP.NET Server Controls

Validation controls test user input, set an error state, and produce error messages. They do not change the flow of page processing — for example, they do not bypass your code if they detect a user input error. Instead, you test the state of the controls in your code before performing application-specific logic. If you detect an error, you prevent your own code from running; the page continues to process and is returned to the user with error messages.

> **Security Note** By default, the Web Forms page automatically validates that malicious users are not attempting to send script or HTML elements to your application. As long as this validation is enabled, you do not need to explicitly check for script or HTML elements in user input. For more information, see Scripting Exploits.

You can test for a general, page-wide state, and you can test the state of individual controls. Typically, you do these things in the event handlers that you create for a page.

> **Note** Validation information is not available during a page's initialization or load stage. However, you can call the **Validate** method manually during **Page_Load** and then test the **IsValid** property. For details about page states, see Web Forms Page Processing.

To test for a general error state

- In your code, test the page's **IsValid** property. This property rolls up the values of the **IsValid** properties of all the validation controls on the page (using a logical AND); if any one validation control is set to invalid, the page's property will return false.

  The following example shows the event handler for a button. The code tests the **IsValid** property of the entire page. Note that there is no need for an else clause, because the page will be returned automatically to the browser and the validation controls will display their own error messages.

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As Object, _
ByVal e As System.EventArgs) _
Handles Button1.Click
   If Me.IsValid Then
      ' Perform database updates or other logic here
   End If
End Sub

// C#
void Button1_Click(object sender, System.EventArgs e)
{
   if (IsValid)
   {
      // Perform database updates or other logic here.
   }
}
```

To test for the error state of individual controls

- Loop through the page's Validators collection, which contains references to all the validation controls. You can then examine the **IsValid** property of each validation control.

  > **Note** If you want to perform this check during **Page_Load**, you must manually call the **Validate** method first.

  The following example shows how you can get information about individual validation controls.

```
' Visual Basic
If (Me.IsPostBack) Then
   Me.Validate()
   If (Not Me.IsValid) Then
      Dim msg As String
      ' Loop through all validation controls to see which
```

```
        ' generated the error(s).
        Dim oValidator As IValidator
        For Each oValidator In Validators
           If oValidator.IsValid = False Then
              msg = msg & "<BR>" & oValidator.ErrorMessage
           End If
        Next
        Label1.Text = msg
     End If
  End If

  // C#if (this.IsPostBack)
  {
     this.Validate();
     if (!this.IsValid)
     {
        string msg = "";
        // Loop through all validation controls to see which
        // generated the errors.
        foreach (IValidator aValidator in this.Validators)
        {
           if (!aValidator.IsValid)
           {
              msg += "<br>" + aValidator.ErrorMessage;
           }
        }
        Label1.Text = msg;
     }
```

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls | Validating Programmatically for ASP.NET Server Controls

Controlling Validation Error Message Display for ASP.NET Server Controls

You can display error message text in four ways:

Display method	Description
In-line (only)	Next to the control (in the place where the validation control is located).
Summary (only)	In a separate summary of all errors, which is available only when the user submits the page. Optionally, the errors can appear in a message box (the option to use a message box is available only if the user is using Internet Explorer 4.0 or later).
In-line and summarized	The error message can be different in the summary and in place. You can use this option to show a shorter error message in place with more detail in the summary, or to show an error glyph next to the input field and an error message in the summary.
Custom	You can create your own error message display. For details, see Displaying Custom Error Messages for ASP.NET Server Controls.

You also have options for specifying the format and layout of error messages. For details, see Formatting Validation Error Messages for ASP.NET Server Controls.

If you want to display summarized error messages, you need to add a control to the page.

To add summarized error messages

1. Add a **ValidationSummary** control to the page at the location where you want to display the collected error messages.
2. Set the summary control's **DisplayMode** property to format the error messages, using one of the following values defined in the **ValidationSummaryDisplayMode** enumeration:

Value	Description
BulletList	(Default) Each message appears as a bulleted item.
List	Each message appears on its own line.
SingleParagraph	Each message appears as a sentence in a paragraph.

3. Optionally set the control's **HeaderText** property to provide a title or header for the error messages.

Choosing in-line and summary display involves setting different combinations of properties in the individual validation controls.

To choose in-line and summary error display

1. If you want to display summary errors, add a **ValidationSummary** control as described in the procedure above.
2. Set the **ErrorMessage**, **Text**, and **Display** properties of the individual validation controls according to the following table:

Option	ValidationSummary control required?	Property settings on validation control
Inline only	No	**Display** = **Static** or **Dynamic** **ErrorMessage** = (error text) or **Text** = (error text)
Summary only (including optional message box)	Yes	**Display** = **None** **ErrorMessage** = (error text) or **Text** = (error text)
Inline and summary (including optional message box)	Yes	**Display** = **Static** or **Dynamic** **ErrorMessage** = (error text for summary) **Text** = (in-line error text or glyph)

If the user is working with Internet Explorer 4.0 or later, summarized error messages can also appear in a message box.

To display summarized error messages in a message box

- Set the **ShowMessageBox** property of the **ValidationSummary** control to **true**.

When the user submits the page, errors are displayed both in the summary control and in the message box. If you do not want the errors to be displayed in the summary control, set the ShowSummary property to **False**.

Introduction to Validating User Input in Web Forms | Formatting Validation Error Messages for ASP.NET Server Controls | Specifying Layout for In-Place Messages On ASP.NET Server Controls

Formatting Validation Error Messages for ASP.NET Server Controls

You can control the format — font, size, and so on — of error text, or you can substitute a glyph for error text. For example, you can set the Text property of a validation control to an asterisk (*). When an error occurs, the asterisk will appear on the page in the location of the validation control (for example, beside the invalid field). You can include a detailed error message in the ErrorMessage property of the validation control and add a ValidationSummary control to the page; the detailed ErrorMessage property text will appear on the page in the location of the ValidationSummary control.

Validation controls support the same properties as other controls for specifying their appearance.

To format error messages

- Set validation control properties such as the following:

Property	Description
ForeColor	The color of the error message text.
BackColor	The color behind the text.
Font	The font face, size, weight, and so on.
BorderWidth, **BorderColor**, and **BorderStyle**	The size and color of a border around the error message.
CSSStyle and **CSSClass**	Style settings that are used if the user is working with a browser that supports CSS style sheets.

> **Note** Some of the settings you make with these properties may not be supported in all browsers.

You can provide formatting within an error message by using HTML elements in the text for the **ErrorMessage** and **Text** properties. For example, to apply italics to only one word in the error message, you can enclose the word in <I> and </I> tags.

> **Note** To display reserved HTML characters within the error message text, encode them. For example, to display "<", use the character sequence
> <
> .

If you are displaying validation errors in a summary, you can specify that a glyph appear in place of the individual validation control.

To display glyphs next to input controls

1. Set the **ErrorMessage** property of each validation control to the error text that should appear in the **ValidationSummary** control.
2. Set the **Text** property of each validation control to the glyph to display. The glyph can consist of any valid HTML, including text (such as an asterisk) or an image.

> **Note** The glyph is displayed in place of the validation control. It is up to you to lay out the validation control in such a way that the glyph displays properly.

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls | Specifying Layout for In-Place Messages On ASP.NET Server Controls

Specifying Layout for In-Place Messages On ASP.NET Server Controls

When an error message appears on the page, it becomes part of the layout of the page. You can specify that the layout be fixed — the error message does not change the page layout when it appears — or dynamic. For details about layout options, see Validation Error Message Layout for ASP.NET Server Controls.

To specify fixed or dynamic layout for client error messages

- Set the **Display** property of each validation control to a layout option defined by the **ValidatorDisplay** enumeration:

Option	Description
None	Used when you are using only the summary control
Static	For a fixed layout
Dynamic	For a dynamic layout

Note Internet Explorer 4.0 or later is necessary to view static layout.

Disabling Validation for ASP.NET Server Controls

You might want to bypass validation under certain circumstances. For example, if you have a "Cancel" button or a navigation button on a page, the page should be able to post even if the user did not fill out all the validated fields correctly. You can set an ASP.NET server control to bypass validation on both the server and the client, or just on the client.

> **Security Note** By default, the Web Forms page performs request validation to ensure that user input does not include script or HTML elements. You can disable this feature explicitly. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

Disabling Server-Side and Client Side Validation

You can specify that individual controls on a Web Forms page cause a postback without triggering a validation check.

To cause a specific control to bypass validation

- Set the control's **CausesValidation** property to **false**.

  The following example shows how you can create a Cancel button that does not perform a validation check:

```
<asp:Button id="Button1" runat="server"
   Text="Cancel" CausesValidation="False">
</asp:Button>
```

You can also disable a validation control, so that it is not rendered to the page at all and no validation takes place using that control.

To disable a validation control

- Set the validation control's **Enabled** property to **false**.

Disabling Client-Side Validation Only

If you want to perform validation on the server but not on the client, you can set an individual validation control to not emit client-side script. This is useful if dynamic updating on the client creates problems with the layout of the page, or if you want to execute some server code before validation takes place.

To disable client-side validation

- Set the validation control's **EnableClientScript** property to **false**.

See Also

Introduction to Validating User Input in Web Forms | Client-Side Validation for ASP.NET Server Controls

Displaying Custom Error Messages for ASP.NET Server Controls

You do not have to use the validation control to output a response when the **IsValid** property is false. On both the client and server side you can create a custom response, such as a color change in a control or a font change for text on a label.

To display custom validation messages

- In the **Page_Load** event handler, call the **Validate** method, then check the page's **IsValid** property and conditionally add text or a control, or change the properties (for example, color) of a control. The following example displays the label "All entries are valid" when the **IsValid** property is **true**, and "There are one or more invalid entries" when the property is **false**.

```
' Visual Basic
If (Me.IsPostBack) Then
   ValidationControl1.Validate()
   If (ValidationControl1.IsValid) Then
      lblOutput.Text = "All entries are valid."
   Else
      lblOutput.Text = "There are one or more invalid entries."
   End If
End If

// C#
if (this.IsPostBack)
{
   ValidationControl1.Validate();
   if (ValidationControl1.IsValid)
   {
      lblOutput.Text = "All entries are valid.";
   }
   else
   {
      lblOutput.Text = "There are one or more invalid entries.";
   }
}
```

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls | Formatting Validation Error Messages for ASP.NET Server Controls

Validating Programmatically for ASP.NET Server Controls

By default, the validation controls perform validation automatically when the page is posted back to the server, after page initialization (that is, after view-state and postback data have been processed) and before your event-handling code is called. The controls might also perform validation in the browser if the browser supports the necessary client script.

However, there are times when you might want to perform validation yourself under program control. When you do, you are doing what the page does automatically: calling a validation control's **Validate** method, which causes the control to perform its validation and set its **IsValid** property. You might validate programmatically under these circumstances:

- If validation values are not set until run time. For example, if you are working with a **RangeValidator** control, you might be setting its **MinimumValue** and **MaximumValue** properties at run time based on values entered by the user. In this case, default validation does not work, because at the time that the page calls the validation controls to perform validation, there is insufficient information in the **RangeValidator** control.
- If you want to check the validity of a control (or of the page as a whole) in the **Page_Load** event handler. At that stage of page processing, the validation controls have not yet been invoked, so the **IsValid** property of the page or of individual controls is not set. (It will throw an exception if you try to get its value.) However, if you want to check validity, you can programmatically call validation.
- If you are adding controls (either input controls or validation controls) at run time.

More generally, you can validate programmatically any time when you want to have precise control over when validation is carried out.

> **Security Note** By default, the Web Forms page automatically validates that malicious users are not attempting to send script or HTML elements to your application. If you have disabled this feature, you can call the Request.ValidateInput method yourself.

To validate programmatically

1. In an event handler, write code to set the validation control properties that you want to change.
2. Call the validation control's **Validate** method.

   The control will perform its check and, if an error is detected, will set the **IsValid** property of the control and the page to **False**. When the page is returned to the user, error messages will be displayed as usual.

   The following example shows how you can set properties programmatically. In this case, a Web Forms page is set up to take reservations at a resort that features a free tour during every visit. Users must enter an arrival date and a departure date, and then schedule the tour during their visit. A **RangeValidator** control is used to ensure that the user entered a typical date format, and that the tour date falls between the arrival and departure dates.

   > **Note** If a user enters a value that cannot be converted to a date, the validator control will throw an exception that must be handled. This example, however, does not include error handling.

   The arrival and departure dates come from two **TextBox** Web server controls on the page, txtArrival and txtDeparture. The tour date is entered in a third **TextBox** control, txtTourDate, which is validated by the **RangeValidator** control.

   > **Note** When validating programmatically, you should disable client script so that the control will not show the wrong error message before your server-side validation code executes. For details, see Disabling Validation for ASP.NET Server Controls.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As _
System.EventArgs) Handles Button1.Click
   RangeValidator1.MinimumValue = txtArrival.Text
   RangeValidator1.MaximumValue = txtDeparture.Text
   RangeValidator1.Type = ValidationDataType.Date
   RangeValidator1.Validate()
   If Not RangeValidator1.IsValid Then
      RangeValidator1.ErrorMessage = "The tour date must " & _
      "fall between the arrival and departure dates."
   End If
```

```
End Sub

//C#
private void Button1_Click(object sender, System.EventArgs e)
{
   RangeValidator1.MinimumValue = txtArrival.Text;
   RangeValidator1.MaximumValue = txtDeparture.Text;
   RangeValidator1.Type = ValidationDataType.Date;
   RangeValidator1.Validate();
   if (!RangeValidator1.IsValid)
   {
      RangeValidator1.ErrorMessage = "The tour date must " +
      "fall between the arrival and departure dates.";
   }
}
```

Introduction to Validating User Input in Web Forms | Controlling Validation Error Message Display for ASP.NET Server Controls | Testing Validity Programmatically for ASP.NET Server Controls

Walkthrough: Validating User Input in a Web Forms Page

As with any input form, Web Forms pages require you to make sure that users are entering information that is valid, is in the right format, and so on. To make this common task easier, you can use validation controls created especially for Web Forms pages. Validation controls allow you to check for required entries, data types, ranges, patterns, and specific values by simply setting properties. The controls perform checking automatically and include a variety of ways for displaying error information to users. For an overview, see Web Forms Validation.

> **Security Note** By default, the Web Forms page automatically validates that malicious users are not attempting to send script to your application. For more information, see Scripting Exploits.

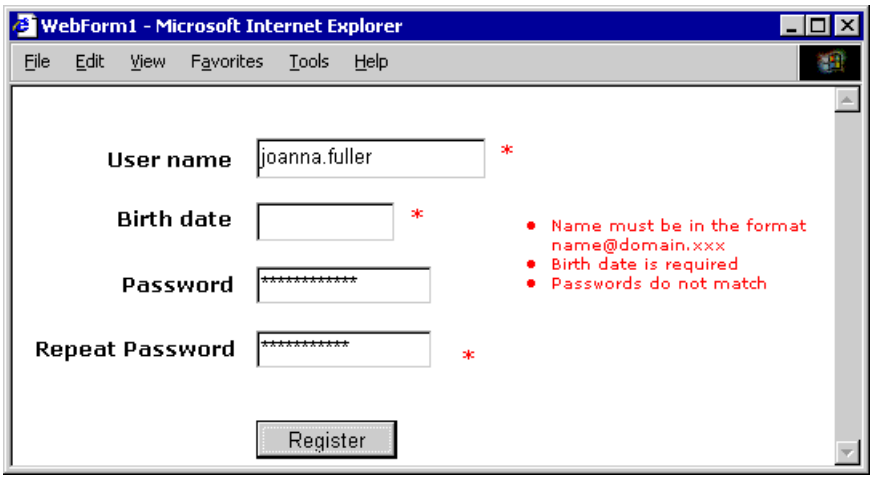
This walkthrough illustrates a simple Web Forms page that you might create as a simple registration page. The page includes text boxes to allow users to enter a login name, a birth date, a password, and a repeat of the password. You will add validation controls to the page to be sure that users enter values into all the boxes and that the values are formatted correctly.

In order to complete this walkthrough, you will need sufficient permissions to be able to create ASP.NET Web application projects on the computer where your Web server is.

The walkthrough is split into a number of smaller pieces:

- Creating the basic form by creating a project and Web Forms page and adding the input controls and labels.
- Adding the validation controls. You will validate for required entries, that the user has entered a valid login name and date, and that the passwords match.
- Testing.

When you have finished the walkthrough, you will have a form that looks similar to the following.



Creating the Basic Form

You can start by creating a form with input controls on it.

Creating the Form

The first step is to create a form that you will later add validation controls to. Start by creating a new Web application project and Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, and then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

      When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new

Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

Tip If you have trouble creating a Web application project, see Web Access Failed Dialog Box.

3. If the page is not already in grid mode, use the Properties window to set the document object's **pageLayout** property to **GridLayout**.

   This step is optional, but makes it easier to lay out the form. If you prefer to work in flow layout, you can, but you might have to make minor adjustments to where the controls appear on the page. The page will work the same way in either case.

Adding Input Controls

For this walkthrough, which assumes that you are creating a simple registration page, you will add controls to allow users to enter a name (an e-mail address), a birth date, and a password. Users enter the password twice to confirm it.

To add the controls

1. From the **Web Forms** tab of the Toolbox, add the following controls to the form, setting their **ID** property as indicated:

Control	Purpose	ID
TextBox	Enter user name	**txtName**
TextBox	Enter birth date	**txtBirthdate**
TextBox	Enter password	**txtPassword**
TextBox	Repeat password to confirm it	**txtPasswordAgain**
Button	Submit form	**btnRegister** Set the button's **Text** property to Register.

2. Set the **TextMode** property of the two password boxes to **Password** so that they display stars (*) as users type in them.
3. Add labels in front of the text boxes to indicate their function. If the Web Forms page is in grid mode, add **Label** controls in front of each text box and set their **Text** property. If the page is in flow mode, simply type static text in front of each box.
4. Adjust the font, size, and layout of the controls to your liking. For details about layout, see Positioning HTML Elements in Design View.

Adding Validation Controls

Now that you have created the input form, you can add validation. You do so by adding validation controls to the form, one control for each validation test you want to perform. (In all, you will add seven validation controls to cover all the tests you should perform plus a control to display errors.) The validation tests you will perform are these:

- Required fields. You want to be sure that users enter values into all four boxes.
- Name format. For this walkthrough, you will check that the user's login name follows the pattern of typical e-mail names: *name@domain.xxx*. In this walkthrough, you will not validate that the e-mail name the user provides belongs to a valid e-mail account.
- Date format. You will validate that the user's entry for birth date is a valid date. (In this walkthrough, you will not validate that the date falls within a specific range.)
- Password match. You will validate that the passwords that the user supplies in the two password boxes match.

Checking For Required Fields

You want to be sure that users enter values into all four text boxes — that is, all four text boxes are required fields.

To check for required fields

1. From the **Web Forms** tab of the Toolbox, drag a **RequiredFieldValidator** control onto the form, next to the **txtName** text box.
2. Select the validation control and in the Properties window, set the following properties.

Property	Setting
ControlToValidate	`txtName` This indicates that the validator will check the contents of the name field.

Text	`*` (star) This is the text that will be displayed where the validator control is now. (It is common to put a red star next to an input box containing errors.)
ErrorMessage	`Email name is required.` This text will be displayed in a summary on the page.

3. If you like, set the font, color, and formatting properties for the validation control. These properties affect how errors are displayed.
4. Repeat Steps 1 through 3 for the other three text boxes, creating three more **RequiredFieldValidation** controls with the following settings.

Control	Settings
RequiredFieldValidator2	• **ControlToValidate**: Set to `txtBirthdate` • **Text**: `*` • **ErrorMessage**: `You must enter a birth date.`
RequiredFieldValidator3	• **ControlToValidate**: Set to `txtPassword` • **Text**: `*` • **ErrorMessage**: `You must enter a password.`
RequiredFieldValidator4	• **ControlToValidate**: Set to `txtPasswordAgain` • **Text**: `*` • **ErrorMessage**: `Re-enter the password to confirm it.`

Checking Name Format

For the walkthrough, you are assuming that the user should enter an e-mail address as the registration name. Although you cannot check that the name represents a valid e-mail account, you can check that the name conforms to typical e-mail address format (such as *name@domain.com*). This catches entry errors that users often make, such as forgetting to enter the ".com" portion of their e-mail address.

To check for patterns such as this, you use a validator control that incorporates a regular expression. If you know regular expression syntax, you can create your own pattern-matching expressions. However, you can also choose from a list of predefined regular expressions, including those to check for e-mail addresses, phone numbers, and postal codes.

When you add this validation control, you will have two controls for the name box; the contents of the box must pass both checks to be considered valid. When you have multiple validators for a single control, you generally want them to display their text (typically, a star) in the roughly the same location, no matter which validation check fails. You can specify this by setting the validator control's Display property. For more information, see Validation Error Message Layout for ASP.NET Server Controls.

To check name format

1. From the **Web Forms** tab of the Toolbox, drag a **RegularExpressionValidator** control next to the **txtName** box.
2. Select the validation control and in the Properties window, set the following properties.

Property	Setting
ControlToValidate	`TxtName`
Text	`*` (star)
ErrorMessage	`Name must be in the format name@domain.xxx.`
ValidationExpression	From the list, select **Internet E-mail Address**. Note that this sets the property value to a regular expression.

Checking Date Format

You want to be sure that users enter a valid date for the birth date field. You can do this with a validation control that performs two functions at once: it checks that the user has entered a date (by data type) and it compares that the date is later than a specified minimum date.

To check date format

1. From the **Web Forms** tab of the Toolbox, drag a **CompareValidator** control next to the **txtBirthdate** box.
2. Select the validation control and in the Properties window, set the following properties.

Property	Setting
ControlToValidate	`TxtBirthdate`
Text	* (star)
ErrorMessage	`Birth date is not a valid date.`
ValueToCompare	`1900/01/01` (Or any other minimum date.) **Note** Enter the date to compare in the format yyyy/mm/dd; this ensures that it will be interpreted properly for all culture settings. Users must enter the date using only numbers for the month.
Operator	`Greater Than`
Type	`Date`
Display	**Dynamic**

Checking for Password Match

As is done often, your registration form asks users to type their password twice to confirm that that is what they want to enter. You can check this using the same validation control you used for the date — a comparison control — but instead of checking against a specific value, you will compare the value of one field — the second password box — against what they typed into the first password box.

> **Security Note** Using a **TextBox** control set for passwords can help ensure that other people will not be able to determine a user's password if they observe the user entering it. However, the password text entered is not encrypted in any way, and you should protect it as you would any other confidential data. For example, for maximum security when posting a form with a password in it, you might use secure sockets layer (SSL) and encryption. For more information, see Web Application Security at Run Time.

To check for password match

1. From the **Web Forms** tab of the Toolbox, drag a **CompareValidator** control next to the **txtPasswordAgain** box.
2. Select the validation control and in the Properties window, set the following properties.

Property	Setting
ControlToValidate	`TxtPasswordAgain`
Text	* (star)
ErrorMessage	`The passwords do not match.`
ControlToCompare	`TxtPassword`
Operator	`Equal`
Display	**Dynamic**

Displaying Validation Errors

One step remains. You have configured the validation controls so that they display a red star next to an input box containing an error. However, this might not give users enough information. For example, they might realize that they have entered a bad registration name, but might not be able to figure out what is wrong with it.

To display details about validation errors, you can use a summary control. The control displays the value of the **ErrorMessage** property of any validation control that has detected an error. If there is more than one error, the summary control can display them all, either as bulleted items, in a simple list, or as a paragraph of text.

To display validation errors

1. From the **Web Forms** tab of the Toolbox, drag a **ValidationSummary** control onto the form. Position the control someplace where it has room to display several lines of text.
2. If you want to display errors in a format other than bulleted items, select a different display option for the **DisplayMode** property.

3. Set the **Font** and **ForeColor** properties to format the error message text.
4. You are done adding validation controls. Now you can test to see how they work.

Testing Validation

You want to test the Web Forms page with different values to see the effect of the validation controls.

To test the validation controls

1. In Solution Explorer, right-click the name of your form and choose **View in Browser**.
2. When the page is displayed, enter various values into the boxes. To check the birth date, enter a date that is invalid for the locale of your Web server.

   Each time you make an error, a star should appear next to the box containing the error.

3. Click **Register**.

   If there are any errors, the error message text appears in the summary control. (Red stars appear and disappear immediately as you work with the fields.)

   > **Note** Required fields are checked the first time only when you submit the form, so that users are not forced to enter data into the form in a specific order. However, after the first time the form is submitted, errors are reported until the field is filled in.

If you are not seeing the errors you expect to see, review the settings for each of the validation controls and try again.

Next Steps

The validation you added in this walkthrough to the Web Forms page illustrates the basic concepts of Web validation controls. There is more you can do with validation controls, both with their basic functionality as well as in code. You could expand on the walkthrough in these ways:

- Check that the user enters a birth date earlier than today by adding a second **CompareValidator** control and setting its operator to **LessThan** and its comparison value to today. You can use a data-binding expression to set the value. Although you are not binding the validator control to data, you are taking advantage of the fact that data binding expressions are evaluated before the control is rendered. The ASP.NET syntax for the control might look like this:

  ```
  <asp:CompareValidator id=c1
  ValueToCompare='<%# DateTime.Today.ToShortDateString() %>'
  ControlToValidate="txtBirthDate" Operator="LessThan" Type="Date" Text="*" runat="server"
  />
  ```

  > **Note** You must call the validator control's **DataBind** method to resolve the expression.

- Check the length of the password to be sure it meets a certain minimum number of characters. You can do this with a **RegularExpressionValidator** control. There is no predefined expression that checks for a minimum number of characters. You can use an expression such as the following, which requires five or more characters:

  ```
  ^[\w]{5,}
  ```

- Test validation in code. Each validation control sets a flag that you can test programmatically. This complements the visual feedback that the controls provide; by testing for valid input in code, you can determine how to proceed (or not proceed) in your application. For details, see Validating Programmatically for ASP.NET Server Controls.
- Learn about the security issues associated with Web Forms. For details, see Overview of Web Application Security Threats.

Introduction to Validating User Input in Web Forms

Client Script in Web Forms Pages

If you know that the users of your Web Forms pages have uplevel browsers, you can add functionality to your pages by including client script that runs in the browser, apart from the server controls you are using.

> **Note** For information about uplevel and downlevel browsers, see ASP.NET Server Controls and Browser Capabilities.

Because client script runs in the browser, you can include it in the page for operations that manipulate the look of the page and require quick response time. Examples include enabling and disabling controls, performing mouseover operations, animating elements on the page, and so on.

As a rule, client script runs entirely separately from the server code that you create for your Web Forms page, and you can therefore create whatever script is required in your page. However, a few ASP.NET server controls depend on client script for their functionality. This does not prevent you from using client script when working with those controls, but you do need to understand the interaction of your client script with the client script that is produced by these controls.

The ASP.NET server controls that depend on being able to run client script include:

- The LinkButton and HtmlButton server controls require script. (This is not true for the Button Web server control or the HtmlInputButton or HtmlInputImage controls.)
- By default, the Calendar control implements month navigation and day selection using **LinkButton** controls. If you set control properties to allow users to select a day, week, or month, or if you allow users to navigate to other months, then the **Calendar** control will generate client script. If you use the **Calendar** control simply to display a single month with no selection or navigation, the control does not require client script.
- Any Web server control whose **AutoPostBack** property is set to **true**; the client script is required so that the control will post the page.
- The Web validation controls, which require client script to support client-side validation. If the client does not support script, validation will run on the server only.

> **Note** For information on creating event handlers that run in both client script and in server code, see ASP.NET Server Control Event Model.

The client script required is automatically generated and sent as part of the page. It is compatible with all types of browsers that support at least ECMAScript (JScript, JavaScript) — that is, it does not depend on the advanced scripting capabilities of Dynamic HTML (DHTML).

> **Note** Some validation features can take advantage of DHTML if it is available in the browser, but DHMTL is not required.

Users sometimes disable script in a browser as a security measure. If they have, the functionality provided by client script is lost. This disables some controls, such as the **LinkButton** control, entirely, and disables the functionality of the **AutoPostBack** property. Validation is only partially affected; validation still functions, but users do not get the immediacy and performance of client-side validation.

Controls You Can Use on Web Forms Pages

This section discusses what you can do with each of the Web server controls available in Visual Studio. If you want to use HTML server controls in your application, see HTML Server Controls.

> **Note** You can also create output for mobile devices. To do so, you use the same ASP.NET page framework, but you create Mobile Web Forms instead of Web Forms pages and use controls specifically designed for mobile devices. For details, see Creating ASP.NET Mobile Web Applications.

In This Section

AdRotator Web Server Control
Describes the AdRotator, which cycles through a series of clickable ad banners.
Button Web Server Controls
Describes the Button controls, which allow the user to send a command, such as submitting a form to a server.
Calendar Web Server Control
Describes the Calendar control, which allows users to view and select dates.
CheckBox and CheckBoxList Web Server Controls
Describes these option controls, which provide a way for users to switch between true/false, yes/no, or on/off options.
DataGrid Web Server Control
Describes the DataGrid control, a multi-column, data-bound grid which offers extensive design-time customization.
DataList Web Server Control
Describes the DataList control, which displays rows of database information in customizable format.
DropDownList Web Server Control
Describes the DropDownList control, which enables users to select from a single-selection list box.
HyperLink Web Server Control
Describes the Hyperlink control, which provides a means of creating and manipulating links on a Web page from server code.
Image Web Server Control
Describes the Image control, which allows you to display images on a Web Forms page and manage the images in your own code.
Label Web Server Control
Describes the Label control, which provides a way to display text under programmatic control in a Web Forms page.
Literal Web Server Control
Describes the Literal control, which renders static text into a Web page without adding any HTML elements.
ListBox Web Server Control
Describes the ListBox control, which allows users to select one or more items from a predefined list.
Panel Web Server Control
Describes the Panel control, which provides a container within the page for other controls.
PlaceHolder Web Server Control
Describes the PlaceHolder control, which enables you to place an empty container control in the page and then dynamically add child elements to it at run time.
RadioButton and RadioButtonList Web Server Controls
Describes these option controls, which allow users to select one item from a short, predefined list.
Repeater Web Server Control
Describes the Repeater control, which is a data-bound container control that produces a list of individual items.
Table, TableRow, and TableCell Web Server Controls
Describes these controls, which are used to construct general-purpose tables on a Web Forms page.
TextBox Web Server Control
Describes the TextBox control, which provides a way for users to type information into a Web Forms page, including text, numbers, and dates.
Validation Web Server Controls
Describes the controls you can use to validate input on your Web Forms pages.
XML Web Server Control
Describes the XML control, which reads XML and writes it into a Web Forms page at the location of the control.
Simple HTML Controls

Controls for Displaying Lists On Web Pages

You can use several different Web server controls to display data in list form. Except for the Table control, these controls are bound to a data source. They produce one item — an entry — for each record in the data source.

The following table lists the Web server controls that display lists and differences between them.

Type of Control	Purpose	Features
Table	• General-purpose, programmable table.	• Can display any combination of HTML text and controls. • Supports a **TableCell** control that can be set to display information. Does not use templates for display. • Is not inherently data-bound. • Exposes a model for dynamically creating rows (**TableRow** controls) and cells (**TableCell** controls).
Repeater	• Simple, read-only output	• Has no built-in support for selecting or editing items. • Has no default appearance; you must lay out the list by creating templates. The list can be vertical, horizontal, all on one line, or in any format you specify. • Has no default paging; all data is displayed in a single list. • Can define separators between elements using a template. • Supports custom functionality that can be applied to items (for example, specifying an "Add to shopping cart" button for each item).
DataList	• List output with editing • Non-tabular lists (for example, comma-delimited lists) • Easily customizable output	• Has a table appearance by default, but can be configured to show any list output. • Can customize look of list extensively. • Has an auto-format option. • WYSIWYG template editing. • Supports styles for custom look of items. • Can define separators between elements using a template. • Has editable contents (contents displayed in text boxes or other controls, based on data type of bound data). • Supports single selection. Multiple selection requires custom code. • Supports either horizontal (columns) or vertical (rows) layout of the data items. • Has no default paging; all data is displayed in a single list. • Supports custom functionality that can be applied to items (for example, specifying an "Add to shopping cart" button for each item).
DataGrid	• Full-featured list output with editing • Paged reporting	• Has a grid appearance by default. • Can customize look of grid extensively. • Has an auto-format option. • Can specify output using bound columns, columns of buttons or hyperlinks, and custom columns created using templates. • Has no separator template. However, the grid renders in a table, and you can specify table border size and color. • Supports WYSIWYG template editing. • Items support styles for custom look. • Can edit, update, and delete contents. • Supports single selection. Multiple selection requires custom code. • Has optional paged output. • Supports sorting. • Supports custom functionality that can be applied to items (for example, specifying an "Add to shopping cart" button for each item).

AdRotator Web Server Control

The **AdRotator** Web Server Control cycles through a series of clickable ad banners, and allows some ads to be weighted more heavily than others. Ads can either be linked to the control using an XML file with a predefined schema or by creating your own custom logic.

The following topics provide information that you will find useful in learning to work with the **AdRotator** control.

Introduction to the AdRotator Web Server Control

Advertisements on Web pages typically take the form of ad banners — .gif files or similar images — that when clicked redirect the user to the advertisers' Web pages. In order to generate ads on your Web page you will need the image files and accompanying URLs.

Using the AdRotator Web server control you can display and cycle through a series of ad banners. The **AdRotator** automates the cycling process, changing the displayed ad each time the page is refreshed. Ads can be weighted to control the priority level of banners making it possible to have certain ads display more often than others. You can also write custom logic that cycles through the ads.

Use the **AdRotator** control to retrieve and display ads with one of two methods:

- Create an XML file containing references to ad banners and their associated properties.
- Write your own logic to select an ad banner in the **AdCreated** event.

XML File Format

One method of storing ad banner image locations, URLs for redirection, and associated properties is to put the information in an XML file. By using the XML file format you can create and maintain a list of advertisements without having to change the code in your application when a change is made to an advertisement. The XML file can be created using the **Ad Rotator Schedule File** template in the XML designer. For details, see Creating an Ad List for the Ad Rotator Web Server Control.

Filtering Ads by Keyword

In the XML file you can assign categories to ads and then configure the **AdRotator** control to show ads according to filter criteria you specify. For example, if a specific **AdvertisementFile** contains categories for both banks and hardware stores you may only want the page to display ads related to banks. By setting the **KeywordFilter** property to "banks" the hardware store ads will be filtered out.

If a filter is specified then one of two situations can result:

- If the ad source is an XML advertisement file, then ads with a matching keyword will be selected.
- If the ad source is an XML advertisement file, but no match exists in the ad file, then the **AdRotator** will display a blank image and a trace warning will be generated.

Tracking Ad Response

The **AdRotator** control does not inherently provide a way to gather statistics about which ads users have clicked, how many times an ad has been clicked, and so on. However, because you have control over the URL to which the ad points, you can add tracking logic to your application for the ads. A typical way to do this is to point all ads to a tracking page that first gathers the statistics you want, and then jumps to the ad's destination page. For details, see Tracking Ad Responses for the AdRotator Control.

Adding AdRotator Controls to a Web Forms Page | Creating an Ad List for the Ad Rotator Web Server Control | Selecting Ads in an AdRotator Web Server Control at Run Time

Adding AdRotator Controls to a Web Forms Page

First you add the **AdRotator** control to a page, and then link it to the ads you wish to display. Link ads to the control either by using a separate XML file containing the ad information or by linking the ads to the control within an event handler at run time.

To add an AdRotator control to a Web Forms page

1. In Design view, drag an **AdRotator** control from the **Web Forms** tab of the Toolbox onto the page.
2. Link the **AdRotator** to an XML advertisement file:
   a. Select the **AdRotator**, open the Properties window, and then click the ellipsis button (...) next to the **AdvertisementFile** property.

      The **Select Advertisement XML File** dialog box appears.

   b. Navigate to the location of the XML file holding the information about your ads and click **Open**.

      Note If the **AdvertisementFile** property is set to an XML file, then the **AdCreated** event occurs after the ad has been selected.

      Note Alternately, you can set the ad properties in the **AdCreated** event. For details, see Selecting Ads in an AdRotator Web Server Control at Run Time.

Introduction to the AdRotator Web Server Control | Creating an Ad List for the Ad Rotator Web Server Control | Selecting Ads in an AdRotator Web Server Control at Run Time

Creating an Ad List for the Ad Rotator Web Server Control

You can create an ad list for the **AdRotator** control in the XML designer using the **Ad Rotator Schedule File** as the target schema. The following attributes can be included in the files:

- **ImageUrl** The URL of the image to display
- **NavigateUrl** The URL of the page to navigate to when the **AdRotator** control is clicked.
- **AlternateText** The text to display if the image is unavailable.
- **Keyword** The category of the ad that can be used to filter for specific ads.
- **Impressions** A numeric value that indicates the likelihood of how often the ad is displayed. The total of all impressions values in the XML file may not exceed 2,048,000,000 - 1

All attributes are optional.

To create an ad list using the XML designer

1. From the **Project** menu select **Add New Item**.
2. Select **XML file** from the **Templates** window and give it a unique name.
3. From the **TargetSchema** property in the Properties window, select **Ad Rotator Schedule File** from the list.
4. Insert a new `<Ad>` element within the `<Advertisements>` element for each ad you want to include in the ad list.
5. Set the necessary properties for each ad from among the following attributes:

```
<ImageUrl>...</ImageUrl>
<NavigateUrl>...</NavigateUrl>
<AlternateText>...</AlternateText>
<Keyword>...</Keyword>
<Impressions>...</Impressions>
```

6. Save the file.

Adding AdRotator Controls to a Web Forms Page | Introduction to the AdRotator Web Server Control | XML Designer | Tracking Ad Responses for the AdRotator Control

Selecting Ads in an AdRotator Web Server Control at Run Time

You can dynamically select ads by creating custom logic within an **AdCreated** event handler. If you have more than one **AdRotator** control in your project it is better to create a global event handler that responds to all of your **AdRotator** controls. In this way the logic for rotating the ads in each control can be handled by the same event.

To select ads using the AdCreated event

1. Create an **AdCreated** event handler for the control.

   The second parameter passed in the handler contains a reference to the ad being created.

2. Set properties of the ad object to specify the image and navigation URLs of the ad to deploy.

   The following example shows how you can set the **ImageUrl**, **NavigateUrl**, and **AlternateText** properties of an **AdRotator** control (AdRotator1) in the **AdCreated** event handler:

```
' Visual Basic
Public Sub AdRotator1_AdCreated(ByVal sender As Object, ByVal e As System.Web.UI.WebContr
ols.AdCreatedEventArgs) Handles AdRotator1.AdCreated
    e.ImageUrl = "images/msft_ad.gif"
    e.NavigateUrl = "http://www.microsoft.com/"
    e.AlternateText = "Where do you want to go today?"
End Sub

// C#
protected void AdRotator1_AdCreated (object sender,
   System.Web.UI.WebControls.AdCreatedEventArgs e)
{
   e.ImageUrl = "images/msft_ad.gif";
   e.NavigateUrl = "http://www.microsoft.com/";
   e.AlternateText = "Where do you want to go today?";
}
```

If you have several **AdRotator** controls in your project, you can create a single global event handler in the Global.asax file. This event handler can then be used by each control.

To create a global event handler to handle more than one AdRotator control

1. In the Global.asax file, create an event handler for the **GlobalAdCreated** event.

   The following example retrieves information from an imaginary commercial ad server called **AcmeAdServer** by adding an XML Web service (**AdService**) as a Web reference to the project. The AdService has a method called **GetNextAd** that contains the logic for specifying which ad is shown.

   The **GlobalAdCreated** event passes the **KeywordFilter** of the **AdRotator** control as a keyword into the **AdService.GetNextAd()** method, which returns the **ImageUrl**, **NavigateUrl**, and **AlternateText** from the **AdInfo** (a structure declared within the **AdService**) for the next ad to be displayed. The **GlobalAdCreated** event is called each time the page refreshes.

```
' Visual Basic
Public Shared Sub GlobalAdCreated(ByVal sender As Object, ByVal e As System.Web.UI.WebCon
trols.AdCreatedEventArgs)

    Dim ai As AcmeAdServer.AdInfo
    Dim ws As New AcmeAdServer.AdService()
    Dim keyword As String

    keyword = CType(sender, AdRotator).KeywordFilter
    ai = ws.GetNextAd(keyword)
```

```
    e.ImageUrl = ai.ImageUrl
    e.NavigateUrl = ai.NavigateUrl
    e.AlternateText = ai.AltText

End Sub

// C#
public static void GlobalAdCreated(Object sender, System.Web.UI.WebControls.AdCreatedEven
tArgs e)
{
   AcmeAdServer.AdInfo ai;
   AcmeAdServer.AdService1 ws = new AcmeAdServer.AdService1();
   String keyword;

   keyword = ((AdRotator)sender).KeywordFilter;
   ai = ws.GetNextAd(keyword);

   e.ImageUrl = ai.ImageUrl;
   e.NavigateUrl = ai.NavigateUrl;
   e.AlternateText = ai.AltText;
}
```

2. In the Web Form's load event, link the **AdRotator** controls' **AdCreated** events to the event handler defined in Global.asax.

```
' Visual Basic
Protected Sub Page_Load(ByVal Sender As System.Object, ByVal e As System.EventArgs) Handl
es MyBase.Load
    AddHandler AdRotator1.AdCreated, AddressOf Global.GlobalAdCreated
    AddHandler AdRotator2.AdCreated, AddressOf Global.GlobalAdCreated
End Sub

// C#
protected void Page_Load(object sender, EventArgs e)
{
        AdRotator1.AdCreated += new System.Web.UI.WebControls.AdCreatedEventHandler (Glob
al.GlobalAdCreated);
        AdRotator2.AdCreated += new System.Web.UI.WebControls.AdCreatedEventHandler (Glob
al.GlobalAdCreated);
}
```

Adding AdRotator Controls to a Web Forms Page | Introduction to the AdRotator Web Server Control | Tracking Ad Responses for the AdRotator Control

Tracking Ad Responses for the AdRotator Control

The **AdRotator** control does not inherently provide a way to gather statistics about which ads users have clicked, how many times an ad has been clicked, and so on. Ads displayed by the **AdRotator** control are effectively nothing more than hyperlinked images, with no special features for gathering statistics.

However, because you have control over the URL to which the ad points, you can add tracking logic to your application for the ads. A typical way to do this is to point all ads to a tracking page that first gathers the statistics you want, and then jumps to the ad's destination page.

Redirecting Ads to a Tracking Page

When you redirect to a tracking page, not only must you jump to the redirection page, but you must also be sure that the redirection page has the right information for gathering statistics. An easy way to do this is to include the necessary information in a query string.

> **Note** Query strings are appended to the URL of the redirection page and can be seen (and possibly manipulated) by users. If it is important that users not see this information (for example, for security reasons), you should encode the query string or use an alternative way to pass information about the ad to the redirection page. For information about persisting data between pages, see Web Forms State Management.

To redirect ads to a tracking page

- In the **NavigateURL** property of an individual ad, specify a URL that includes:
  - The name of your redirection page
  - Information that allows you to identify the ad
  - The page to which the ad ultimately points

  The following example shows an entry for a single ad from an XML ad list file. In this example, the redirection page is AdRedirector.aspx. The ad identifier and ultimate target page are specified as a query string.

  > **Note** Because the ampersand (&) is a reserved character in XML, the query string includes the entity reference
  > &
  > instead.

```
<Ad>
<ImageUrl>Widgets.gif</ImageUrl>
<NavigateUrl>AdRedirector.aspx?ad=Widgets&amp;target=http://msdn.microsoft.com/widgets/</
NavigateUrl>
<AlternateText>Microsoft Widgets</AlternateText>
<Keyword>computers</Keyword>
<Impressions>1</Impressions>
</Ad>
```

Gathering Statistics and Jumping to the Destination Page

The tracking page you specify performs two functions: it gathers statistics about the ads that users have clicked, then it redirects again to the ad's ultimate destination page. This generally means that the tracking page has no UI of its own.

How you gather statistics depends on your application requirements. As a minimum, you will probably count the number of times an ad has been clicked and store this information in a database.

To gather statistics and jump to the destination page

1. In the `Page_Load` handler of the tracking page, extract information about the ad that has been clicked and the destination page.
2. Store or otherwise process the ad information, as required by your application.
3. Call the Response.Redirect method to jump to the destination page.

   The following example shows a simple `Page_Load` handler that counts the number of times an ad has been clicked and stores the count in the Application state object, using the name of the ad as the key. (In your applications, you are likelier to

store this information in a database.) After updating the count, the code jumps to the destination page.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
      ByVal e As System.EventArgs) Handles MyBase.Load
   Dim source As String = Request.QueryString("ad")
   Dim redirect As String = Request.QueryString("target")
   Dim adcounter As Integer
   If Application(source) Is Nothing Then
      adcounter = 0
   Else
      adcounter = CType(Application(source), Integer)
   End If
   adcounter += 1
   Application(source) = adcounter
   Response.Redirect(redirect)
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   String source = Request.QueryString["ad"];
   String target = Request.QueryString["target"];
   int adcounter;
   if(Application[source] == null)
   {
      adcounter = 0;
   }
   else
   {
      adcounter = (int) Application[source];
   }
   adcounter += 1;
   Application[source] = adcounter;
   Response.Redirect(target);
}
```

Button Web Server Controls

Buttons in a Web Forms page allow the user to send a command. They submit the form to the server and cause it to be processed along with any pending events.

Web server controls include three types of buttons: a standard command button (Button control), a hyperlink-style button (LinkButton control), and a graphical button (ImageButton control). All three provide similar features, but each offers a different look.

The following topics provide information that you will find useful in learning to work with the button Web controls.

Introduction to the Button Web Server Controls

Buttons on a Web Forms page allow users to indicate that they are finished with the form or want to perform a specific command. Web server controls include three kinds of buttons with different appearances.

Types of Buttons

You can create these types of Web server control buttons:

Control	Description
Button Web server control	Presents a standard command button, rendered as an HTML submit button.
LinkButton Web server control	Renders as a hyperlink in the page. However, it contains client-side script that causes the form to be posted back to the server. (You can create a true hyperlink using the HyperLink Web server control.)
ImageButton Web server control	Allows you to specify a graphic as a button. This is useful for presenting a rich button appearance. **ImageButton** controls also pinpoint where in the graphic a user has clicked, which allows you to use the button as an image map.

> **Note** You can also use the HtmlButton and HtmlInputButton controls to create buttons on the page that are programmable in server code. For details about the differences between HTML and Web server controls, see Introduction to ASP.NET Server Controls.

Button Events

All three types of buttons cause a form to be submitted to the server when the user clicks them. This causes the page to be processed and any pending events to be raised in server-based code. The buttons can also raise their own Click events that you can write event handlers for.

Buttons in Container Controls

Button Web server controls are often used in other controls, such as in the DataList, DataGrid, and Repeater list controls. When they are, you generally respond to their events differently than when they are standing alone on a form. When a user clicks a button in a container control, the event message is bubbled to the container control, where it raises a container-specific event. For example, in the **DataList** control, a button often raises the **DataList** control's ItemCommand event (rather than a **Button** control's Click event).

Because the list Web server controls can contain many different buttons, you can specify an argument to pass along with the event when the event is bubbled to the container control. You can then test for this argument to see which button was clicked.

Binding Data to the Controls

You can bind the Web server button controls to a data source in order to control their property settings dynamically. For example, you can set the buttons' Text property via data binding.

For details, see Data Binding Single-Value Web Server Controls at Design Time.

Adding Button Web Server Controls to a Web Forms Page | Responding to Button Web Server Control Events | Creating Graphical Button Web Server Controls

Adding Button Web Server Controls to a Web Forms Page

Adding buttons to a page is a simple process. Because buttons execute commands, it can be useful to define an access key for a button.

Adding an **ImageButton** control to a page is slightly more involved than working with other button types. For details, see Creating Graphical Button Web Server Controls.

To add button Web server controls to a Web Forms page

1. In **Design** view, drag a **Button** or **LinkButton** control from the **Web Forms** tab of the Toolbox onto the page.
2. Set the caption by setting the control's Text property.

To make it easier for users to click a button, you can define an access key for the button. Users can then press ALT plus the access key to choose the button.

> **Note** Access keys are not supported in all browsers.

To define a button's access key

- Set the AccessKey property to a single character. For example, to make the access key ALT+B, specify B as the value of the **AccessKey** property.

  > **Note** In Windows applications, access keys are typically indicated on a button using an underlined character. This marking is not available for button Web server controls due to restrictions in HTML. If you want to be able to display the access key for a button, you can use the HtmlButton control.

See Also

Setting Web Server Control Properties Programmatically | Responding to Button Web Server Control Events

Creating Graphical Button Web Server Controls

An **ImageButton** control allows you to present a picture as a clickable control.

To create a graphical button

1. In **Design** view, drag an **ImageButton** Web server control to the page.
2. Set the button's **ImageUrl** property to point to an image file (.gif, .jpg, and so on).

   You can point to an image file anywhere using a URL or UNC path. However, only files that are part of the project are deployed with the application. Therefore, it is recommended that you add the image file for your button to the project.

See Also

Determining Coordinates in an ImageButton Web Server Control

Determining Coordinates in an ImageButton Web Server Control

You can use an **ImageButton** Web Server control as an image map — that is, you can capture the precise x and y coordinates where a user clicked within the image. This allows you to perform different tasks based on where the user clicked.

Coordinate information is sent as part of the event-argument object for the **ImageButton** control's Click event.

To determine the coordinates where a user clicks

1. Create an event handler for the **ImageButton** control's **Click** event. The event-argument object for the method must be of type ImageClickEventArgs Class.
2. In the control's **Click** event handler, get the X and Y properties of the event-argument object.

   The x and y coordinates are expressed in pixels, where the upper left corner of the image is (0,0).

The following example shows how you can determine where the user clicked in a graphic that is 100 by 100 pixels. The code gets the x and y coordinates of the user's click. It then compares them against predetermined values to see if the user clicked in a particular quadrant. The results are displayed in a Label control.

```
' Visual Basic
Private Sub ImageButton1_Click(ByVal sender As System.Object, _
      ByVal e As System.Web.UI.ImageClickEventArgs) _
      Handles ImageButton1.Click
   Dim msg as String = ""
   Dim x As Integer = e.X
   Dim y As Integer = e.Y

   ' The button graphic is assumed to be 100x100 pixels.
   ' This checks coordinates against predetermined values that
   ' make up quadrants of the picture.
   If x >= 50 And y >= 50 Then
      msg = "Southeast"
   ElseIf x >= 50 And y < 50 Then
      msg = "Northeast"
   ElseIf x < 50 And y >= 50 Then
      msg = "Southwest"
   ElseIf x < 50 And y < 50 Then
      msg = "Northwest"
   End If
   Label1.Text = msg ' Display results
End Sub

// C#
private void ImageButton1_Click(object sender, System.Web.UI.ImageClickEventArgs e)
{
   // Label text
   string msg = "";
   // X coordinate from click argument
   int x = e.X;
   // Y coordinate from click argument
   int y = e.Y;

   // The button graphic is assumed to be 100x100 pixels.
   // This checks coordinates against predetermined values that
   // make up quadrants of the picture.
   if(x>=50 && y>= 50)
   {
   msg = "Southeast";
   }
   else if(x >=50 && y < 50)
   {
   msg = "Northeast";
   }
   else if(x < 50 && y >= 50)
```

```
    {
    msg = "Southwest";
    }
    else if(x < 50 && y < 50)
    {
    msg = "Northwest";
    }
    // Display results.
    Label1.Text = msg;
  }
```

Creating Graphical Button Web Server Controls

Responding to Button Web Server Control Events

When a **Button**, **LinkButton**, or **ImageButton** Web server control is clicked, the current page is submitted to the server, where it is processed.

To respond to a button event

- Create an event handler for one of the following events:
  - The page's **Page_Load** event. Because the button always posts the page to the server, this method will always run. Use the **Page_Load** event when it is not important which button was clicked, only that the form was submitted.
  - The button's Click event. Write an event handler for this event when it is important to know which button was clicked.

    > **Note** If you are working with an **ImageButton** control and want to know the x and y coordinates of the user's click, you must create an event handler for this event. For details, see Determining Coordinates in an ImageButton Web Server Control.

The following example shows how you can respond when a user clicks a **Button** Web server control. The method displays a message in a Label Web server control.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button1.Click
   Label1.Text="You clicked a button"
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   Label1.Text="You clicked a button.";
}
```

The following example shows how you can respond to a button click in a **Page_Load** event handler. The method tests the page's IsPostBack property to determine whether this is the first time the page has been processed or whether it was submitted by a button click.

```
' Visual Basic
Private Sub Page_Load(ByVal Sender As System.Object, ByVal e _
    As System.EventArgs) Handles MyBase.Load
    If Not IsPostback Then
        ' This is called the first time the page has loaded.
        ' The user will not have been able to click any buttons yet.
    Else
        ' This is called if the form has been posted back, possibly
        ' by a button click.
        Me.Label1.Text = "You clicked a button."
    End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   if (!IsPostBack)
   {
      // Evals true first time browser hits the page.
   }
   else
   {
```

```
      // This is called if the form has been posted back, possibly
      // by a button click.
      this.Label1.Text = "You clicked a button.";
   }
}
```

The following example shows a simple four-function integer calculator. By binding all the buttons (Add, Subtract, Multiply, and Divide) to the same method, you can handle all the calculations in one place and avoid repetitive code. Binding the buttons to the **Calculate** method is accomplished by using the **AddHandler** method in Visual Basic, and by using the += operator in C#. To ensure that the input values are integers, you could add error-handling code to the **Calculate** method or use the validation controls available for Web Forms.

```
' Visual Basic
' Set the CommandName property of the buttons to "Add",
' "Subtract", "Multiply", and "Divide".
Private Sub Page_Load(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
MyBase.Load
   AddHandler Me.btnAdd.Click, AddressOf Calculate
   AddHandler Me.btnSubtract.Click, AddressOf Calculate
   AddHandler Me.btnMultiply.Click, AddressOf Calculate
   AddHandler Me.btnDivide.Click, AddressOf Calculate
End Sub

Public Sub Calculate(ByVal sender As Object, ByVal e As System.EventArgs)
   Dim op1 As Integer = CType(Me.TextBox1.Text, Integer)
   Dim op2 As Integer = CType(Me.TextBox2.Text, Integer)
   Dim result As Integer
   Select Case CType(sender, Button).CommandName
      Case "Add"
         result = op1 + op2
      Case "Subtract"
         result = op1 - op2
      Case "Multiply"
         result = op1 * op2
      Case "Divide"
         ' Divide two numbers and return an integer result.
         If op2 > 0 Then
               result = op1 \ op2
         Else
               result = 0
         End If
      Case Else
         ' Error handling code here.
   End Select
   Label1.Text = result.ToString()
End Sub

// C#
// Set the CommandName property of the buttons to "Add", _
// "Subtract", "Multiply", and "Divide".
protected void Page_Load(object sender, EventArgs e)
{
   btnAdd.Click += new System.EventHandler(this.Calculate);
   btnSubtract.Click += new System.EventHandler(this.Calculate);
   btnMultiply.Click += new System.EventHandler(this.Calculate);
   btnDivide.Click += new System.EventHandler(this.Calculate);
}
```

```
protected void Calculate (object sender, System.EventArgs e)
{
   int op1 = Convert.ToInt16(TextBox1.Text);
   int op2 = Convert.ToInt16(TextBox2.Text);
   int result = 0;
   switch(((Button)sender).CommandName)
   {
      case "Add" :
         result = op1 + op2;
         break;
      case "Subtract" :
         result = op1 - op2;
         break;
      case "Multiply" :
         result = op1 * op2;
         break;
      case "Divide" :
         // Integer division.
         if (op2 > 0)
               result = op1 / op2;
         else
               result = 0;
         break;
      default:
         // Error handling code here.
         break;
   }
   Label1.Text = result.ToString();
}
```

Calendar Web Server Control

The Calendar Web server control displays a traditional one-month calendar on your Web Forms pages. Users can use the calendar to view and select dates.

The following topics provide information about the Calendar Web server control and how to use it.

In This Section

Introduction to the Calendar Web Server Control
Provides a general description of the **Calendar** control.
Controlling Month Navigation in a Calendar Web Server Control
Gives directions for specifying whether users can move from month to month.
Controlling User Date Selection in a Calendar Web Server Control
Gives directions for specifying whether users can select a day, a week, or the entire month.
Customizing Calendar Web Server Control Appearance
Gives directions for changing the fonts, colors, size, and other appearance features of the calendar as a whole.
Customizing Individual Days in a Calendar Web Server Control
Gives directions for changing the content or look of individual days programmatically, for example, by creating appointment information.
Formatting Web Calendar Elements Using Styles
Gives directions for customizing the look of specific areas of the calendar, such as today's date, weekend days, and the title bar.
Responding to Date Selection in a Calendar Web Server Control
Gives directions for running code in response to the user selecting one or more dates.
Selecting Dates Programmatically in a Calendar Web Server Control
Gives directions for setting and clearing selected dates in code.
Setting Today's Date Programmatically in a Calendar Web Server Control
Gives directions for adjusting the current date to accommodate different time zones on the server and client.

Customizing the Appearance of ASP.NET Server Controls Using Styles
Gives directions for applying styles to change how controls are displayed.

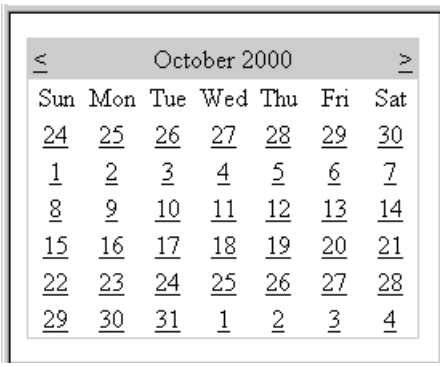
Introduction to the Calendar Web Server Control

The **Calendar** Web server control can serve these purposes:

- **Display and select dates** The control displays a calendar through which users can navigate to any day in any year. Setting the SelectedDate Property property causes a specific date to be highlighted in the control. Optionally, users can move to arbitrary dates by clicking a day or moving from month to month. The calendar can be configured to allow users to select multiple dates, either an entire week or an entire month.

  Typical uses are to graphically display the current date on a daily news Web page, or to allow users to select dates in scheduling applications to order airline reservations, concert tickets, and so on.

  A representation of the Calendar control displaying the month of October

- **Display appointment or other information in a calendar grid** The **Calendar** control can display day-specific details for individual days, such as a to-do list, a schedule of events, or similar information. This feature allows you to display day information from a database.

The **Calendar** control is based around the .NET framework DateTime object, and therefore supports the full range of dates allowed by that object. Effectively, you can display any date between the years 0 and 9999 A.D.

> **Note** In Visual Basic the **Date** data type is equivalent to the .NET framework's DateTime data type.

The **Calendar** control is rendered as an HTML table when the Web Forms page runs. Therefore, a number of the control's properties pertain to various aspects of table formatting. A few of these properties are not fully supported in some older browsers, so some formatting features will not be available in those browsers.

Developing with the Calendar Web Server Control

The following sections contain details about how the **Calendar** control works and an overview of tasks you can accomplish with it.

Displaying and Selecting Dates

The **Calendar** control displays a month of dates at a time, with a total of six weeks appearing at once. Within the control, there are several types of dates that you can work with:

Type of date	Description
Today's date	By default, the current date on the server. However, you can adjust it so that the date appears correctly for a different locale.
Visible date	This date determines what month appears in the calendar. The user can move from month to month on the calendar, thereby changing the visible date without affecting today's date. You can navigate between months by setting the visible date programmatically.
Selected date or dates	This is the date or date range that the user chooses. In the control, the user can choose a single day, week, or month, but can only select contiguous dates. You can also programmatically set the selected dates; in that case, you can set non-contiguous selected dates.

Enabling Date Selection

By default, the calendar allows users to click an individual date to select it. If you are using the control as a read-only calendar, you can disable all date selection.

If day selection is enabled, each day of the calendar contains a LinkButtoncontrol that raises an event when clicked. If you enable week or month selection, a column of links is added to the left side of the calendar to enable the user to specify what week to select.

Customizing the Calendar's Appearance

You can set calendar properties to change the colors, size, text, and other visual features of the calendar. There are a number of ways to do this:

Method	Description
Setting properties	You can set properties to display grid lines, change what day is displayed as the first day of the week, and change the appearance of the month and day names.
Setting extended style properties	You can use properties derived from the Style object to set the appearance of particular elements in the calendar, such as the current date or the title bar containing the month and navigation links. These style properties are supported in browsers that can use cascading style sheets; a reduced set of appearance styles is supported for earlier browsers.
Customizing the rendering of individual days	As the control renders individual days, it raises an event you can handle to modify the stream being rendered to the browser. This is useful not just for changing the appearance of days, but for including custom content on each day as well.

Capturing User Interaction with the Calendar Web Server Control

The **Calendar** control raises an event when the user selects an individual date or range of dates or navigates to a new month. By creating methods for these events, you can determine what day or dates the user has selected and respond appropriately. One response may be to customize the display of that date. In creating a custom display, you can include any HTML elements in the calendar, including other server controls.

Displaying Information from a Database in the Calendar Control

A common scenario is to display information from a database in the calendar. For example, an events calendar is often based out of information kept in a database.

The **Calendar** control does not directly support databinding — that is, you do not bind the calendar as a whole to a data source. Instead, you create a method for the control's **DayRender** event, which is raised as each day in the current calendar month (view) is being rendered. In the method for this event, you can extract information from a data source and add it to the stream being sent to the browser.

Controlling Month Navigation in a Calendar Web Server Control

By default, the calendar displays the month containing today's date. Users can move from month to month in the **Calendar** control by clicking month navigation links (actually, LinkButton Web server controls) in the title bar of the calendar. You can control whether these links are available for the user to click.

You can also navigate programmatically, which is useful if you want to provide an alternate way for users to display a specific month. Finally, you can respond to an event raised when the user navigates.

To enable or disable user month navigation

- Set the **Calendar** control's ShowNextPrevMonth property to **true** or **false**. If **false**, the control does not display the **LinkButton** controls in the title that allow a user to move between months.

  Tip You can change the appearance of the month navigation hyperlinks by setting the NextMonthText, PrevMonthText, NextPrevFormat, and NextPrevStyle properties.

To navigate months programmatically

- Set the control's VisibleDate property to a date in the month you want to display. The date can be any day within that month, but is typically set to the first day of the month. If the **VisibleDate** property is empty (it is set to **DateTime.Empty**), the currently visible month is derived from the value of the TodaysDate property.

  The following example navigates to February, 2000:

  ```
  ' Visual Basic
  Calendar1.VisibleDate = New Date(2000, 2, 1)

  // C#
  Calendar1.VisibleDate = new DateTime(2000, 2, 1);
  ```

  Changing the **VisibleDate** property has no effect on the values of the **TodaysDate**, SelectedDayStyle, or SelectedDates properties.

If month navigation is enabled, the control raises an event when the user moves to another month. You can handle this event in order to replace or amend the default month navigation. For example, if you are using two **Calendar** controls in a trip-planning page, you can prevent the user from setting the start-date month later than the end-date month.

To respond to a month navigation event

- Create a method for the control's VisibleMonthChanged event. When this event is raised, the control has already changed the **VisibleMonth** property by one.

  The **VisibleMonthChanged** event takes a single argument of type **MonthChangedEventArgs**. You can use the following properties of this argument to determine or override what the user is doing:

Property	Description
PreviousDate	The value of the month that was displayed before the user clicked a month-navigation button. You can compare the value of this property to that of the control's **VisibleMonth** property to determine what direction the user is navigating. To cancel the effect of the user's click, set the control's **VisibleDate** property to this value.
NewDate	The value of the month that the user has navigated to. The **VisibleDate** property is updated to this value before the **VisibleMonthChanged** event is raised.

```
' Visual Basic
Public Sub Calendar1_VisibleMonthChanged(ByVal sender As Object, _
   ByVal e As System.Web.UI.WebControls.MonthChangedEventArgs) _
   Handles Calendar1.VisibleMonthChanged

   ' Select the 10th and 25th of each month.
   Calendar1.SelectedDates.Clear()
   Calendar1.SelectedDates.Add(New DateTime(e.NewDate.Year, e.NewDate.Month, 10))
```

```
   Calendar1.SelectedDates.Add(New DateTime(e.NewDate.Year, e.NewDate.Month, 25))
End Sub

// C#
private void Calendar1_VisibleMonthChanged (object sender,
   System.Web.UI.WebControls.MonthChangedEventArgs e)
{
     // Select the 10th and 25th of each month.
     Calendar1.SelectedDates.Clear();
     Calendar1.SelectedDates.Add(new DateTime(e.NewDate.Year, e.NewDate.Month, 10));
     Calendar1.SelectedDates.Add(new DateTime(e.NewDate.Year, e.NewDate.Month, 25));
}
```

Responding to Date Selection in a Calendar Web Server Control

Controlling User Date Selection in a Calendar Web Server Control

You can specify that users can select individual days, individual weeks, or an entire month in the **Calendar** control. Alternatively, you can disable day selection altogether.

To control user date selection

- Set the **Calendar** control's SelectionMode property to one of the values defined in the **SelectionMode** enumeration: **Day**, **DayWeek**, or **DayWeekMonth**. To disable all date selection, set the property to **None**.

  > **Note** Users can only select a single day, a single week, or the whole month. However, in code you can select any arbitrary set of dates. For details, see Selecting Dates Programmatically in a Calendar Web Server Control.

When selection is enabled, whenever the user selects a day, week, or month, the form is submitted and an event is raised for which you can create a method. For details, see Responding to Date Selection in a Calendar Web Server Control.

To allow the user to select a date, the calendar is displayed with links. Individual days contain a link with the date number. If you set the calendar to allow users to select a week or the whole month, an extra column with selection links is added to the left of the calendar.

> **Note** You can also control date selection for individual days. For example, you might specify that users can click specific days of the month, such as holidays. For details about customizing days in this way, see Customizing Individual Days in a Calendar Web Server Control.

You can specify the text for the week and month selection links.

To specify week and month selection link text

- Set the SelectWeekText and SelectMonthText properties to the text you want to use as a navigation link.

  You can also set the font, color, and border style of the column containing the week and month selection links and set styles for days. For details, see Formatting Web Calendar Elements Using Styles.

Customizing Calendar Web Server Control Appearance

Because the **Calendar** control is a complex control made up out of many individual elements, it offers you a wide variety of options for customizing its appearance. In this topic, you can learn about the following customization options:

- Changing General Calendar Appearance
- Changing Day-of-Week Display
- Changing the Month Display and Navigation Links

Changing General Calendar Appearance

You can change the overall appearance of the **Calendar** control, which establishes a default look for the calendar on the page. If you set appearance properties for individual calendar elements, such as today's date, the selected date, and so on, the individual settings are based on the default settings you make for the calendar as a whole. You can also select from predefined Calendar formats.

> **Note** By default, there is no special formatting to indicate today's date on the **Calendar** control. For details about how to set this format, see Formatting Web Calendar Elements Using Styles.

To change the general appearance of the Calendar control

- Set properties as listed in the following table.

To specify	Set this property
Font, text and background color	Font, ForeColor, BackColor
Overall control size	Height, Width
Margins and spacing around individual days	CellPadding, CellSpacing
Color, size, and style (for example, dotted) of bor der and grid lines	• BorderColor • BorderStyle (set to a **BorderStyle** enumeration value: **Dotted**, **D ashed**, **Solid**, and so on). • ShowGridLines (true or false)

To make it easier to establish the appearance of the **Calendar** control, you can select from a variety of predefined Calendar formats.

To select a predefined Calendar control format

1. In **Design** view, select the **Calendar** control.
2. At the bottom of the Properties window, click the **AutoFormat** link to display the **Calendar Auto Format** dialog box.
3. Select a format from the **Name** list.

   You can further customize the predefined format by changing the properties set by the automatic format process.

Changing Day-of-Week Display

By default, the names of the days of the week are displayed in a row at the top of the calendar. You can control the format of this row.

To change the day of week display

- Set properties as listed in the following table.

To	Set this property
Enable or disable the row that deploys days of t he week	ShowDayHeader (true or false)
Specify the format of day names (for example, f ull day name or abbreviation)	DayNameFormat (use a value in the DayNameFormat enumeration: **Full**, **S hort**, **FirstLetter**, **FirstTwoLetters**).
Specify which day starts the week (default is Su nday)	FirstDayOfWeek (use a day defined in the **FirstDayOfWeek** enumeration.
Set color, font, border style and width, and so o n	DayHeaderStyle, which incorporates style information. For details, see Formatting Web Calendar Elements Using Styles.

Changing the Month Display and Navigation Links

The title bar by default displays the name of the current month and a set of navigation links (LinkButton controls) that allow users to move to the next and previous months.

To change month display and navigation links

- Set properties as listed in the following table.

To	Set this property
Remove the title bar altogether (which disables month navigation).	ShowTitle (true or false)
Specify the format of the name of the month (for example, full name or abbreviation) and optionally add a year.	• **MonthNameFormat** (use a value in the **MonthNameFormat** enumeration: **Full** or **Short**). • TitleFormat (set to a value in the **TitleFormat** enumeration: **Month** or **MonthYear**).
Specify the format and text of month navigation links	• NextPrevFormat (use a value in the **NextPrevFormat** enumeration: **Month** or **CustomText**). • NextMonthText and PrevMonthText (set to strings)
Set color, font, border style and width, and so on	TitleStyle, which incorporates style information. For details, see Formatting Web Calendar Elements Using Styles. **Note** You can format the navigation links separately using the **NextPrevStyle** property.

Note You can use HTML tags within the property string.

Formatting Web Calendar Elements Using Styles | Controlling User Date Selection in a Calendar Web Server Control

Customizing Individual Days in a Calendar Web Server Control

By default, days in the **Calendar** control are simply displayed as numbers. (If day selection is enabled, the numbers appear as links. For details, see Controlling User Date Selection in a Calendar Web Server Control.) However, you can customize the appearance and content of individual days, which allows you to:

- Programmatically highlight certain days, for example, showing holidays in a different color.
- Programmatically specify whether an individual day can be selected.
- Add information into the day display, such as appointment or event information.

When the **Calendar** control is creating the output to send to the browser, it raises a DayRender event you can handle. The control calls your method for each day as it is preparing the day for display, and you can then programmatically examine which date is being rendered and customize it appropriately.

The **DayRender** event method takes two arguments, a reference to the control raising the event (the **Calendar** control) and an object of type **DayRenderEvent**. The **DayRenderEvent** object provides access to two additional objects:

- **Cell**, a TableCell object that you can use to set the appearance of an individual day.
- **Day**, which you can use to query information about the day being rendered, control whether the day can be selected, and add content to a day. The **Day** object supports various properties you can use to learn about the day (for example, **IsSelected**, **IsToday**, and so on). It also supports a **Controls** collection that you can manipulate to add content to the day.

To customize the appearance of an individual day

1. Create a method for the **Calendar** control's **DayRender** event. The event should have the following signature:

```
' Visual Basic
Private Sub Calendar1_DayRender(ByVal sender As Object, ByVal e As System.Web.UI.WebContr
ols.DayRenderEventArgs) Handles Calendar1.DayRender
' Additional code here
End Sub

// C#
private void Calendar1_DayRender (object sender, System.Web.UI.WebControls.DayRenderEvent
Args e)
{
   // Additional code here
}
```

2. In the method, set properties of the **Cell** object available via the DayRenderEvent argument, as in the following example:

```
' Visual Basic
   If (e.Day.IsToday) Then
      e.Cell.BackColor = System.Drawing.Color.Red
   End If

// C#
   if (e.Day.IsToday)
   {
      e.Cell.BackColor = System.Drawing.Color.Red;
   }
```

The following example shows a simple but complete method that illustrates how to change the appearance of individual days. The method causes vacation days in the calendar to be rendered in yellow, while weekend days are rendered in green.

```
' Visual Basic
Public Sub Calendar1_DayRender(ByVal sender As Object, ByVal e As System.Web.UI.WebControls.D
ayRenderEventArgs) Handles Calendar1.DayRender
   ' Display vacation dates in yellow boxes with purple borders.
   Dim vacationStyle As New Style()
```

```
    With vacationStyle
       .BackColor = System.Drawing.Color.Yellow
       .BorderColor = System.Drawing.Color.Purple
       .BorderWidth = New Unit(3)
    End With

    ' Display weekend dates in green boxes.
    Dim weekendStyle As New Style()
    weekendStyle.BackColor = System.Drawing.Color.Green

    ' Vacation is from Nov 23, 2000 to Nov 30, 2000.
    If ((e.Day.Date >= New Date(2000, 11, 23)) _
       And (e.Day.Date <= New Date(2000, 11, 30))) Then
       e.Cell.ApplyStyle(vacationStyle)
    ElseIf (e.Day.IsWeekend) Then
       e.Cell.ApplyStyle(weekendStyle)
    End If
 End Sub

 // C#
 private void Calendar1_DayRender (object sender, System.Web.UI.WebControls.DayRenderEventArgs
 e)
 {
    // Display vacation dates in yellow boxes with purple borders.
    Style vacationStyle = new Style();
    vacationStyle.BackColor = System.Drawing.Color.Yellow;
    vacationStyle.BorderColor = System.Drawing.Color.Purple;
    vacationStyle.BorderWidth = 3;

    // Display weekend dates in green boxes.
    Style weekendStyle = new Style();
    weekendStyle.BackColor = System.Drawing.Color.Green;

    if ((e.Day.Date >= new DateTime(2000,11,23)) &&
       (e.Day.Date <= new DateTime(2000,11,30)))
    {
       // Apply the vacation style to the vacation dates.
       e.Cell.ApplyStyle(vacationStyle);
    }
    else if (e.Day.IsWeekend)
    {
       // Apply the weekend style to the weekend dates.
       e.Cell.ApplyStyle(weekendStyle);
    }
 }
```

To specify that an individual day can be selected

- In a method for the **Calendar** control's **DayRender** event, determine what day is being rendered by getting information from the **Day** object in the **DayRenderEvent** argument. Specifically, query the **Date** property of the **Day** object. Then set that day's **IsSelectable** property to true. In the following example, the date September 10, 2001 is made selectable; all other dates are made not selectable.
- July 4, 2000 is made selectable if it is one of `myHoliday`'s days.

```
 ' Visual Basic
 Public Sub Calendar1_DayRender(ByVal sender As Object, _
 ByVal e As System.Web.UI.WebControls.DayRenderEventArgs) _
 Handles Calendar1.DayRender
    Dim myAppointment As Date = New Date(2000, 9, 10)
    If (e.Day.Date = myAppointment) Then
       e.Day.IsSelectable = True
    Else
       e.Day.IsSelectable = False
    End If
```

```
End Sub

// C#
private void Calendar1_DayRender(object sender, System.Web.UI.WebControls.DayRenderEventA
rgs e)
{
   DateTime myAppointment = new DateTime(2001,9,10);
   if (e.Day.Date == myAppointment)
   {
      e.Day.IsSelectable = true;
   }
   else
   {
      e.Day.IsSelectable = false;
   }
}
```

To add content to an individual day

- In a method for the **Calendar** control's **DayRender** event, add any valid Web Forms page element (including HTML) to the **Controls** collection of the **Day** object from the **DayRenderEvent** argument.

  The following example displays holidays. The holidays are created as a two-dimensional array during page load; holiday descriptions are loaded into the elements corresponding to their date. In the **DayRender** event method, each day is compared against the holiday array. If the corresponding element of the holiday array contains something, a label control is created with the holiday text and added into the **Controls** collection for that day.

```
' Visual Basic
' Add to the declarations section of the form class.
Dim holidays(13, 32) As String

' Add to form load.
holidays(1, 1) = "Birthday"
holidays(2, 14) = "Anniversary"

Public Sub Calendar1_DayRender(ByVal sender As Object, _
   ByVal e As System.Web.UI.WebControls.DayRenderEventArgs) _
   Handles Calendar1.DayRender

   If e.Day.IsOtherMonth Then
      e.Cell.Controls.Clear()
   Else
      Dim aDate As Date = e.Day.Date
      Dim aHoliday As String = holidays(aDate.Month, aDate.Day)
      If (Not aHoliday Is Nothing) Then
         Dim aLabel As Label = New Label()
         aLabel.Text = "<br>" & aHoliday
         e.Cell.Controls.Add(aLabel)
      End If
   End If
End Sub

// C#
// Add this to the class members of the form.
string[,] holidays = new String[13,32];

// Add this to the Page_Load event.
holidays[1,1] = "Birthday";
holidays[2,14] = "Anniversary";
```

```
// Add this to the DayRender event.
string aHoliday;
DateTime theDate = e.Day.Date;
aHoliday = holidays[theDate.Month,theDate.Day];
if (aHoliday != null)
{
   Label aLabel = new Label();
   aLabel.Text = " <br>" + aHoliday;
   e.Cell.Controls.Add(aLabel);
}
```

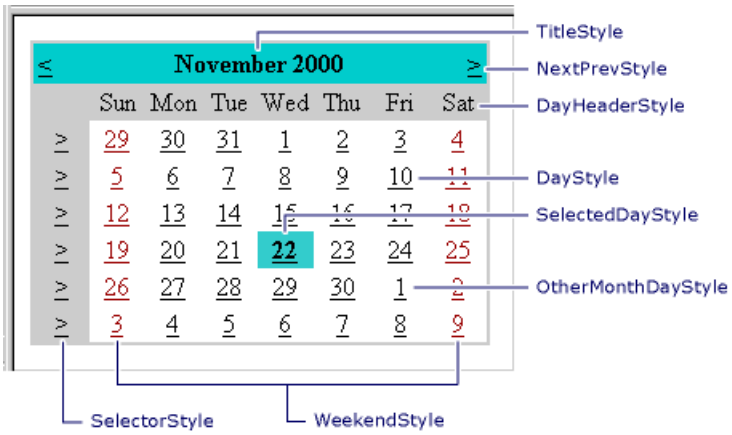
Customizing Calendar Web Server Control Appearance | Controlling User Date Selection in a Calendar Web Server Control | Controlling Month Navigation in a Calendar Web Server Control

Formatting Web Calendar Elements Using Styles

The **Calendar** control, like all Web server controls, allows you to use styles to specify the appearance of the control, including aspects such as font, color, borders, and so on. For general information about using styles with Web server controls, see Customizing the Appearance of ASP.NET Server Controls Using Styles.

> **Note** Styles are not fully supported in all browsers.

To allow you flexibility in customizing the appearance of the calendar output, the **Calendar** control supports styles for a number of discrete elements that make up the calendar grid. The following diagram displays a calendar with all optional elements displayed.



The following table describes each of the elements that you can control using styles.

Calendar Element	Description
DayStyle	Days of the current month. Weekends, today, and the selected day can have different styles (see below).
DayHeaderStyle	Row above the calendar where the names of the days appear.
NextPrevStyle	Sections at the left and right ends of the title bar where the month navigation LinkButtons are.
OtherMonthDayStyle	Days from the previous and next month that appear on the current month view.
SelectedDayStyle	The day selected by the user.
SelectorStyle	The column to the left containing links for selecting a week or the whole month.
TitleStyle	Title bar at the top of the calendar containing the month name and month navigation links. If **NextPrevStyle** is set, it overrides the extreme ends of the title bar.
TodayDayStyle	Today's date.
WeekendDayStyle	Weekend days.

To set calendar element styles in the Web Forms Designer

1. In **Design** view, select the **Calendar** control.
2. In the Properties window, locate the style element to set, such as **DayStyle**, and then expand it to display all style settings.

   > **Tip** If you display properties by category, all the style elements appear together under **Style**.

3. Change the style settings you want to change. Many style settings, such as color and border settings, allow you to select settings from a drop-down list.

You can also set style elements at run time in code.

To set calendar element styles programmatically

- Set properties of individual style elements using the following syntax:

  ```
  Calendar1.StyleName.Property = setting
  ```

  The following examples illustrate some typical style settings for the **Calendar** control:

  ```
  ' Visual Basic
  Calendar1.DayStyle.Font.Size = New FontUnit(10)
  ```

```
Calendar1.TitleStyle.ForeColor = System.Drawing.Color.Red

// C#
Calendar1.DayStyle.Font.Size = new FontUnit(10);
Calendar1.TitleStyle.ForeColor = System.Drawing.Color.Red;
```

Note For details about setting properties, see Setting ASP.NET Server Control Properties.

Customizing Individual Days in a Calendar Web Server Control

Responding to Date Selection in a Calendar Web Server Control

If the **Calendar** control's SelectionMode property is set to anything other than **None**, the user can select a day or a range of dates. You can detect and respond to the user's choice.

To respond to a date selection

- Create a method for the **Calendar** control's SelectionChanged event with the following signature:

```
' Visual Basic
Private Sub Calendar1_SelectionChanged(ByVal sender As System.Object, ByVal e As System.E
ventArgs) Handles Calendar1.SelectionChanged

// C#
private void Calendar1_SelectionChanged (object sender, System.EventArgs e)
```

> **Note** The event is raised only if the date selection is changed by user action in the control. For instance, if the user clicks the same date twice, the second click does not raise an event. The event is also not raised if you set a date range programmatically.

Information about date selection is available in these properties:

Property	Description
SelectedDate	A single date. If the user has selected a single date, this property contains that date. If the user has selected multiple dates, this property contains the first date in the range.
SelectedDates	A collection containing all the dates selected. The dates in this collection are ordered and unique. Because the **Calendar** control does not allow the user to select multiple individual dates, the dates in the collection are also sequential.

To determine how many dates are selected

- Get the value of the **Count** property of the **SelectedDates** collection, as shown in the following example.

```
' Visual Basic
Public Sub Calendar1_SelectionChanged(ByVal sender As Object, _
   ByVal e As System.EventArgs) _
   Handles Calendar1.SelectionChanged

   Text1.Text = "You selected " _
      & Calendar1.SelectedDates.Count.ToString() _
      & " date(s)."
End Sub

// C#
private void Calendar1_SelectionChanged (object sender, System.EventArgs e)
{
   Text1.Text = String.Format("You selected {0} date(s).",
      Calendar1.SelectedDates.Count);
}
```

If you've determined that the user has selected multiple dates, you can get the range.

To get the date range of a multi-date selection

1. Get the count of selected dates using the Count property of the **SelectedDates** property.
2. Get the first date in the collection, and then get the last date by extracting the date at the index of the count -1. The following example displays the first and last dates in TextBox controls on the page.

```
' Visual Basic
Public Sub Calendar1_SelectionChanged(ByVal sender As Object, _
   ByVal e As System.EventArgs) _
```

```
   Handles Calendar1.SelectionChanged

   With Calendar1.SelectedDates
      If .Count > 1 Then
         Dim firstDate As Date = .Item(0).Date
         Dim lastDate As Date = .Item(.Count - 1).Date
         TextBox1.Text = firstDate.ToString()
         TextBox2.Text = lastDate.ToString()
      End If
   End With
End Sub

// C#
private void Calendar1_SelectionChanged (object sender,
   System.EventArgs e)
{
   SelectedDatesCollection theDates = Calendar1.SelectedDates;
   if (theDates.Count > 1)
   {
      DateTime firstDate = theDates[0];
      DateTime lastDate = theDates[theDates.Count-1];
      TextBox1.Text = firstDate.ToString();
      TextBox2.Text = lastDate.ToString();
   }
}
```

To get the time span of a multi-date selection

- Create a TimeSpan object and set it to the difference between the last and first dates in the **SelectedDates** collection, and then get the **TimeSpan** object's Days property.

```
' Visual Basic
Public Sub Calendar1_SelectionChanged(ByVal sender As Object, _
   ByVal e As System.EventArgs) Handles Calendar1.SelectionChanged
   With Calendar1.SelectedDates
      Dim days As Integer
      Dim firstDate As Date = .Item(0).Date
      Dim lastDate As Date = .Item(.Count - 1).Date
      ' The Subtract method returns a TimeSpan object.
      days = lastDate.Subtract(firstDate).Days + 1
      TextBox1.Text = "You have selected " & days.ToString() & " day(s)."
   End With
End Sub

// C#
private void Calendar1_SelectionChanged (object sender,
   System.EventArgs e)
{
   SelectedDatesCollection theDates = Calendar1.SelectedDates;
   TimeSpan timeSpan = theDates[theDates.Count-1] - theDates[0];
   TextBox1.Text =
      String.Format("You have selected {0} day(s).", timeSpan.Days + 1);
}
```

Setting Today's Date Programmatically in a Calendar Web Server Control |
Selecting Dates Programmatically in a Calendar Web Server Control

Selecting Dates Programmatically in a Calendar Web Server Control

You can set date selections in your own code, either a single date or a range of dates. In contrast to user selection in the control on a page, you can select multiple non-sequential dates in code.

Note Setting a date programmatically does not raise the SelectionChanged event.

To select a single date

- Set the control's SelectedDate property to an expression of type **DateTime**.

```
' Visual Basic
Calendar1.SelectedDate = Date.Today

// C#
Calendar1.SelectedDate = DateTime.Today;
```

Note If you set the **SelectedDate**, all the dates in SelectedDates are effectively cleared.

To select a range of dates

- Call the **Add** method of the control's **SelectedDates** collection. You can add dates in any order, because the collection will order them for you. The collection also enforces uniqueness and will therefore ignore a date you add if the date is already in the collection.

  The following example sets the selection to every Wednesday in the month of February, 2000.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, _
    ByVal e As System.EventArgs) Handles Button1.Click

   With Calendar1.SelectedDates
      .Clear()
      .Add(New Date(2000, 2, 2))
      .Add(New Date(2000, 2, 9))
      .Add(New Date(2000, 2, 16))
      .Add(New Date(2000, 2, 23))
   End With
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   SelectedDatesCollection theDates = Calendar1.SelectedDates;
   theDates.Clear();
   theDates.Add(new DateTime(2000,2,2));
   theDates.Add(new DateTime(2000,2,9));
   theDates.Add(new DateTime(2000,2,16));
   theDates.Add(new DateTime(2000,2,23));
}
```

  The following example selects a sequence of seven dates.

```
'Visual Basic
Dim today As Date = Date.Today
Dim i As Integer
```

```
With Calendar1.SelectedDates
   .Clear()
   For i = 0 To 6
      .Add(today.AddDays(i))
   Next
End With

// C#
DateTime aDate = DateTime.Today;
SelectedDatesCollection theDates = Calendar1.SelectedDates;
theDates.Clear();
for (int i = 0;i <= 6;i++)
{
      theDates.Add(aDate.AddDays(i));
}
```

To clear a date selection

- Call the **Clear** method of the control's **SelectedDates** collection, as in the following example:

```
' Visual Basic

Calendar1.SelectedDates.Clear()

// C#

Calendar1.SelectedDates.Clear();
```

Setting Today's Date Programmatically in a Calendar Web Server Control |
Responding to Date Selection in a Calendar Web Server Control

Setting Today's Date Programmatically in a Calendar Web Server Control

By default, the value of "today" in the **Calendar** control is set to match the date of the server on which the Web Forms page runs. However, you might need to adjust the date to accommodate users who are viewing the page from a different time zone.

To set today's date programmatically

- Set the **Calendar** control's TodaysDate property to a **DateTime** value.

  The following example sets **TodaysDate** to tomorrow and then set the **SelectedDate** to **TodaysDate**. In the browser, the date for tomorrow will be highlighted.

```
' Visual Basic
Dim tomorrow As Date = Date.Today.AddDays(1)
Calendar1.TodaysDate = tomorrow
Calendar1.SelectedDate = Calendar1.TodaysDate

// C#
DateTime tomorrow = DateTime.Today.AddDays(1);
Calendar1.TodaysDate = tomorrow;
Calendar1.SelectedDate = Calendar1.TodaysDate;
```

  The following example shows how you can prompt the user for the correct local date and then use that information to adjust the value of today's date.

```
' Visual Basic
' Add this the declarations section of the page class.
Dim today As Date
Dim tomorrow As Date
Dim yesterday As Date
' Add this to the form Load method.
' The user then selects the current date from the DropDownList.
If Not IsPostback Then
   today = System.Date.Today
   yesterday = Today.AddDays(-1)
   tomorrow = Today.AddDays(1)
   DropDownList1.items.Add(String.Format("{0:dd MMM yyyy}", _
      today))
   DropDownList1.items.Add(String.Format("{0:dd MMM yyyy}", _
      yesterday))
   DropDownList1.items.Add(String.Format("{0:dd MMM yyyy}", _
      tomorrow))
End If

' Add this code to set TodaysDate to the users selected date.
Calendar1.TodaysDate = Date.Parse(DropDownList1.SelectedItem.Text)

// C#
// Add this to the declarations section of the page class.
DateTime today;
DateTime yesterday;
DateTime tomorrow;

// Add this to the Page_Load method.
if (!IsPostBack)
{
   today = System.DateTime.Today;
```

```
    yesterday = today.AddDays(-1);
    tomorrow = today.AddDays(1);
    DropDownList1.Items.Add(String.Format("{0:dd MMM yyyy}",
       today));
    DropDownList1.Items.Add(String.Format("{0:dd MMM yyyy}",
       yesterday));
    DropDownList1.Items.Add(String.Format("{0:dd MMM yyyy}",
       tomorrow));
}

// Add this code to set TodaysDate to the users selected date.
Calendar1.TodaysDate = DateTime.Parse(DropDownList1.SelectedItem.Text);
```

CheckBox and CheckBoxList Web Server Controls

The **CheckBox** and **CheckBoxList** Web server controls provide a way for users to switch between true/false, yes/no, or on/off options.

Because there are two different controls, and because they function somewhat differently, it's important to understand their different purposes. You can refer to the following table to determine which topics pertain specifically to the control you want to work with.

> **Note** Some of the topics listed below for the **CheckBoxList** control do not pertain solely to that control; instead, they are topics that apply to all list Web server controls (ListBox, DropDownList, RadioButtonList, and CheckBoxList).

Introduction to the CheckBox and CheckBoxList Web Server Controls

You can use two types of Web server controls to add check boxes to a Web Forms page: individual CheckBox controls or a CheckBoxList control. Both controls provide a way for users to input Boolean data: true or false, yes or no.

> **Note** You can also use the HtmlInputCheckBox server control to add check boxes to a Web Forms page. For details about the differences between Web and HTML server controls, see Introduction to ASP.NET Server Controls.

CheckBox Control versus CheckBoxList Control

You add individual **CheckBox** controls to a page and work with them singly. Alternatively, the **CheckBoxList** control is a single control that acts as a parent control for a collection of check box list items. It derives from a base ListControl class, and therefore works much like the ListBox, DropDownList, and RadioButtonList Web server controls. For that reason, many of the procedures for working with the **CheckBoxList** control are the same as they are for the other list Web server controls.

Each type of control has advantages. By using individual **CheckBox** controls, you get more control over the layout of the check boxes on the page. For example, you can include text (that is, non-check-box text) between each check box. You can also control the font and color of check boxes individually.

The **CheckBoxList** control is a better choice if you want to create a series of check boxes out of data in a database. (You can still bind an individual **CheckBox** control to data.)

CheckBox Events

Events work slightly differently between individual **CheckBox** controls and the **CheckBoxList** control.

Individual CheckBox Controls

Individual **CheckBox** controls raise an event — CheckedChanged — when users click the control. By default, this event does not cause the page to be posted to the server, but you can have the control force an immediate post by setting the AutoPostBack property to **true**. For details about responding to this event directly, see
Responding to User Selection in a CheckBox Web Server Control.

> **Note** The ability of a **CheckBox** control to post to the server when it is checked requires that the browser support ECMAScript (JScript, JavaScript) and that scripting be enabled on the user's browser.

Whether a **CheckBox** control posts to the server or not, you might not need to create an event handler for the **CheckedChanged** event. You can test which check box is selected when the form has been posted to the server by a control such as a **Button** control. Typically, you create an event handler for the **CheckedChanged** event only if you need to know that the check box was changed.

CheckBoxList Control

In contrast, the **CheckBoxList** control raises a SelectedIndexChanged event when users select any check box in the list. By default, the event does not cause the form to be posted to the server, although you can specify this option by setting the **AutoPostBack** property to true. For details, see Responding to Changes in a List Web Server Control.

As with individual **CheckBox** controls, it is more common to test the state of the **CheckBoxList** control after the form has been posted some other way. For details, see Determining the Selection in a List Web Server Control.

Binding Data to the Control

As with any Web server control, you can bind an individual **CheckBox** control to a data source, and you can bind any property of the **CheckBox** control to any field of the data source. For example, it is typical to set the control's Checked property from information in a database.

You can also bind a **CheckBoxList** control to a data source. In that case, the check boxes each represent a different record in the data source.

For general information about data binding Web server controls, see Introduction to Data Binding in Web Forms Pages. For details about binding the **CheckBoxList** control to data, see Populating a List Web Server Control from a Database.

Adding CheckBox Web Server Controls to a Web Forms Page

You can add a check box to a Web Forms page in two ways:

- By adding an individual **CheckBox** Web server control.
- By adding a **CheckBoxList** control and adding individual list items to the control.

For details about the differences in these approaches, see Introduction to the CheckBox and CheckBoxList Web Server Controls.

> **Note** This topic addresses how to add individual **CheckBox** controls to the page. For details about adding a **CheckBoxList** control, see Adding CheckBoxList Controls to a Web Forms Page.

To add an individual CheckBox control to a Web Forms page

1. In **Design** view, drag a **CheckBox** control from the **Web Forms** tab of the Toolbox onto the page.
2. Specify a caption by setting the Text property.
3. Optionally, change the orientation of the caption by setting the TextAlign property.

See Also

Adding Web Server Controls to a Web Forms Page | Adding CheckBoxList Controls to a Web Forms Page | Adding Controls to a Web Forms Page Programmatically | Customizing the Appearance of ASP.NET Server Controls Using Styles | Setting ASP.NET Server Control Properties

Adding CheckBoxList Controls to a Web Forms Page

When you use a **CheckBoxList** control, you add a single control to the page. Adding items to the control is a separate process that depends on whether you will display a static list in the control or a list generated dynamically at run time. For details, see Adding Items in a List Web Server Control.

> **Note** The procedure for working with individual **CheckBox** Web server controls is different. For details, see Adding CheckBox Web Server Controls to a Web Forms Page.

To add a CheckBoxList control to a Web Forms page

1. In **Design** view, drag the **CheckBoxList** control from the Toolbox onto the page.
2. Optionally, change the orientation of the caption by setting the **TextAlign** property.
3. Optionally, change the layout of the control to display multiple columns. For details, see Setting Layout in a CheckBoxList Web Server Control.

See Also

Introduction to the CheckBox and CheckBoxList Web Server Controls | Adding CheckBox Web Server Controls to a Web Forms Page | Adding Items in a List Web Server Control | Setting Layout in a CheckBoxList Web Server Control | Determining the Selection in a List Web Server Control | Setting the Selection in a List Web Server Control

Getting and Setting a CheckBox Web Server Control Value Programmatically

You can programmatically read or set the value of a **CheckBox** Web server control.

> **Note** If you are working with a **CheckBoxList** control, the procedure for getting and setting the value of a check box is different. For details, see Determining the Selection in a List Web Server Control and Setting the Selection in a List Web Server Control.

To get or set CheckBox Web server control selection

- Get or set the **CheckBox** control's **Checked** property. A value of **true** means the check box is selected.

  > **Note** Testing the value of a check box does not tell you if the user changed the value of the control, only if it is selected. For details about how to check for a change in the control, see Responding to User Selection in a CheckBox Web Server Control.

  In the following example, if the check box `chkCanWeSendEmail` is not selected, the check box `chkSendInHTMLFormat` is automatically cleared as well.

```
' Visual Basic
If chkCanWeSendEmail.Checked = false Then
   chkSendInHTMLFormat.Checked = false
End If

// C#
if(chkCanWeSendEmail.Checked == false){
   chkSendInHTMLFormat.Checked = false;
}
```

See Also

CheckBox Class | CheckBoxList Class | Setting ASP.NET Server Control Properties

Responding to User Selection in a CheckBox Web Server Control

When the user selects a **CheckBox** control, the control raises an event that you can respond to.

> **Note** The **CheckBoxList** control raises events differently than individual **CheckBox** controls. For details, see Responding to Changes in a List Web Server Control.

You might not need to respond directly to the check event of a **CheckBox** control at all. You respond to the event only if it's important to know when the user has changed the check box selection.

If you are only interested in the state of the check box when selected, and not whether it has changed, you can simply test the check box after the form has been posted to the server by a control such as a **Button** control. For details about determining whether a **CheckBox** control is selected, see Getting and Setting a CheckBox Web Server Control Value Programmatically.

To respond to a selection in a CheckBox control

- Create an event handler for the control's CheckedChanged event.

  By default, the CheckedChanged event does not immediately cause the Web Forms page to be posted to the server. Instead, the event is raised in server code the next time the form is posted, as when a **Button** Web server control is clicked. To have the **CheckedChanged** event cause an immediate posting, set the **CheckBox** control's AutoPostBack property to **true**.

  > **Note** The ability of a **CheckBox** control to post to the server when it is checked requires that the browser support ECMAScript (JScript, JavaScript) and that scripting be enabled on the user's browser.

  The following example displays "True" or "False" in a **Label** Web server control to reflect the latest change in a **CheckBox** control.

```
' Visual Basic
Private Sub CheckBox1_CheckedChanged(ByVal sender As _
   System.Object, ByVal e As System.EventArgs) Handles _
   CheckBox1.CheckedChanged
   Label1.Text = "CheckBox1 selection is: " & CheckBox1.Checked
End Sub

// C#
private void CheckBox1_CheckedChanged(object sender, EventArgs e)
{
   Label1.Text = "CheckBox1 selection is: " + CheckBox1.Checked;
}
```

See Also

ASP.NET Server Control Event Model | CheckBox Class | CheckBoxList Class | Specifying Whether Controls Post to the Server

Setting Layout in a CheckBoxList Web Server Control

By default, the **CheckBoxList** control displays a single column of check boxes. However, you can specify any number of columns, and within the columns, you can specify how the items are ordered: vertically (the default) or horizontally. Vertical layout in three columns results in a layout such as the following:

```
A     D     G
B     E     H
C     F
```

Horizontal layout for the same items results in the following layout:

```
A     B     C
D     E     F
G     H
```

To specify column count and ordering

1. Set the **CheckBoxList** control's RepeatColumns property to the number of columns you want.
2. Set the **RepeatDirection** property to **Vertical** or **Horizontal**. If you are setting the property in code, use the RepeatDirection enumeration, as shown in the following example:

```
' Visual Basic
CheckBoxList1.RepeatDirection = RepeatDirection.Horizontal

// C#
CheckBoxList1.RepeatDirection = RepeatDirection.Horizontal;
```

DataGrid Web Server Control

The **DataGrid** Web server control is a multi-column, data-bound grid. Extensive customization is available at design-time using the Property Builder dialog box. At design-time you can build columns that display and edit data, columns that contain Edit, Update, Cancel, and Select buttons, columns that contain custom buttons, and template columns. You can then lay out the template columns in template-editing mode.

The following topics provide information that you will find useful in learning to work with the **DataGrid** control.

Programming Web Forms
Suggests additional topics on working with Web Forms in code.
Introduction to ASP.NET Server Controls
Provides background information on working with controls that you can use on Web Forms.

Introduction to the DataGrid Web Server Control

The DataGrid Web server control displays data in a tabular layout. By default, the **DataGrid** displays data in read-only mode, but the **DataGrid** is also capable of automatically displaying the data in editable controls at run-time. The **DataGrid** control can also create the Select, Edit, Update, and Cancel buttons and programming structure for you through the Property Builder dialog box. Additionally, the **DataGrid** supports paging, though you may also use the custom navigation features of the control to improve performance by controlling the amount of data sent to the client browser.

> **Note** To have complete control over the HTML rendered by the list, use the **Repeater** Web server control. Use the **DataList** control to display data in a non-tabular layout. For more information, see Controls for Displaying Lists On Web Pages.

The following sections introduce the features of the **DataGrid** control.

Binding Data to the Control

The **DataGrid** Web server control must be bound to a data source via its **DataSource** property or it will not be rendered on the page. Typical data sources for the **DataGrid** are the **DataSet** and data readers. You can use data sources available from the Toolbox, such as the **DataSet** or **DataView** class. You can also bind to data sources in code, such as a data reader or an array. The control can use as a data source any class that supports the IEnumerable interface.

When data binding, you specify a data source for the **DataGrid** control as a whole. The grid displays one row — one item — for every row in the data source. By default, the **DataGrid** control generates a bound column for each field in the data source. However, you can pick which fields in the data source generate columns in the grid. For more information on data binding, see Introduction to Data Access in Web Forms Pages.

When the Web page runs, your code must call the control's **DataBind** method to load the grid with data. You call the method again if the data changes (for example, in an event handler) to refresh the grid.

As part of the data binding, you can specify a DataKeyField property. This property allows you to specify information that uniquely identifies each item in the grid. The information does not have to be part of the information displayed in the grid. It can consist of the name of a field in the data source (such as a primary key). You can use this information to update a specific item in the data source. For example, if you set the **DataKeyField** to be **customerId**, you could later update the record where `customerID=DataGrid1.DataKeys[DataGrid1.SelectedIndex]`.

As with other server controls, data binding in the **DataGrid** control is one-way; that is, data binding is read-only. If you are using the grid to allow users to edit the data, you must create your own code to update the data source. After updating the data source, you again bind the data to the data source. The update logic often takes advantage of the **DataKeyField** to locate the correct record using the key value.

For more details about updating data using the **DataGrid** control, see "Editing Items" below. For general information about data binding in server controls, see Data Access in Web Forms Pages.

Format Items

The **Format** tab of the Property Builder dialog box controls the layout of the rows of the **DataGrid**. These settings specify the color, font, and alignment of the rows. The actual control, text, and data contents of the row are specified in the **Columns** tab of the Property Builder. The following items can be configured:

- **DataGrid** These settings are applied to the entire grid. Other item formats override these settings.
- **Header** The Header is the top row of the **DataGrid**, and does not display the row data of the data source. You must indicate in the General tab of the Property Builderwhether you want the Header row to be displayed. It is displayed by default.
- **Footer** The **Footer** is the bottom row of the **DataGrid** and does not display the row data of the data source. You must indicate in the General tab of the Property Builderwhether you want the Footer row to be displayed. It is not displayed by default.
- **Pager** If you are displaying only a few rows of your data source at a time, using the paging abilities of the **DataGrid**, use this item to control the appearance of the paging controls.
- **Items** These four items specify how the data rows will appear. They are:
  - **Normal Items** This format is applied to all the data rows of the table, unless overridden by another item.
  - **Alternating Items** This format is applied to alternating items in the control.
  - **Selected Items** This format is applied to the selected item in the control.
  - **Edit Mode Items** This format is applied to the item being edited.

- **Columns** This item allows you to specify the format of the columns you create in the Columns tab of the Property Builder.

For more information on using item formats, see Specifying Grid Item Format in a DataGrid Web Server Control and Specifying Paging Behavior in a DataGrid Web Server Control.

Columns

The **DataGrid** control allows you to specify the columns it displays in a variety of ways. By default, the columns are generated automatically based on fields in the data source. However, in order to control the content and layout of columns more precisely, you can define the following types of columns:

Type of Column	Description
Bound column	Allows you to specify which data source field to display. Allows you to specify the format of that field, using a .NET formatting expression. For details see Adding Bound Columns to a DataGrid Web Server Control.
Hyperlink column	Displays information as hyperlinks. A typical use is to display data (such as a customer number or product name) as a hyperlink that users can click to navigate to a separate page that provides details about that item. For details see Adding Hyperlink Columns to a DataGrid Web Server Control.
Button column	Allows you to add a button for each item in the grid and define custom functionality for that button. For example, you might create a button labeled "Add to Shopping Cart" that runs your custom logic when a user clicks it. You can also add predefined buttons for Select, Edit, Update, Cancel, and Delete functions. For details see Adding Button Columns to a DataGrid Web Server Control.
Edit, Update, Cancel column	Allows you to create in-place editing. For more details, see "Editing Items" below.
Template column	Allows you to create combinations of HTML text and server controls to design a custom layout for a column. The controls within a template column can be data-bound. Template columns give you great flexibility in defining the layout and functionality of the grid contents, because you have complete control over how the data is displayed and what happens when users interact with rows in the grid. For details see Adding Template Columns to a DataGrid Web Server Control.

For more information about columns, see DataGrid Columns.

Events

The **DataGrid** control supports several events. One of them, the **ItemCreated** event, gives you a way to customize the item-creation process. The **ItemDataBound** event also gives you the ability to customize the **DataGrid** items, but after the data is available for inspection. For example, if you were using the **DataGrid** control to display a to-do list, you could display overdue items in red text, completed items in black text, and other tasks in green text.

The remaining events are raised in response to button or **LinkButton** clicks in grid items. They are designed to help you implement common data manipulation tasks. Four events of this type are supported:

- **EditCommand**
- **DeleteCommand**
- **UpdateCommand**
- **CancelCommand**

The Property Builder dialog box of the **DataGrid** control will build the buttons needed to raise these events at run time. When the user clicks one of the buttons (labeled by default Edit, Delete, Update, or Cancel, respectively), the corresponding event is raised.

The **DataGrid** control also supports the **ItemCommand** event that is raised when a user clicks a button that is not one of the predefined buttons above. You can use this event for custom functionality by setting a button's **CommandName** property to a value you need and then testing for it in the **ItemCommand** event handler. (For example, you could use this approach when selecting an item, as documented in Allowing Users to Select Items in a DataList Web Server Control.)

For a complete list of the events supported by the **DataGrid** control, see DataList Events. For more information about events, see ASP.NET Server Control Event Model. For information on supporting these events with the DataGrid, see Allowing Users to Select Items in a DataGrid Web Server Control, Allowing Users to Edit Items in a DataGrid Web Server Control, and Allowing Users to Delete Items in a DataGrid Web Server Control.

Editing Items

You can allow users to edit the contents of individual rows in a grid item. There are two ways to do this:

- Allow in-place editing. This is the easier way to implement editing. Using the Property Builder, you include a special column in the grid known as an Edit, Update, Cancel column. At run time, each row of the column contains a button labeled "Edit". When a user clicks this edit button, the control automatically redisplays the current row with **TextBox** controls for all columns. The column with the edit button is redisplayed with Update and Cancel buttons. You add code to the **UpdateCommand** and **CancelCommand** events to propagate the changes in the editing controls back to your data source.

  For details, see Allowing Users to Edit Items in a DataGrid Web Server Control.

- Create a custom-editing layout with a template column. You can create columns that display the data in editable controls. This approach allows you to choose which columns can be edited and how the user can edit the data. For example, instead of using a **TextBox** control for true-false data, you might prefer a **ListBox** control with "True" and "False" entries. A template column allows you to put more than one control in a DataGrid cell.

  The template column supports four templates:

  - HeaderTemplate
  - ItemTemplate
  - EditItemTemplate
  - FooterTemplate

  For more information, see Allowing Users to Edit Items in a DataGrid Web Server Control and Allowing Users to Delete Items in a DataGrid Web Server Control.

Sorting

The **DataGrid** Web server control provides a way for you to add sorting to the grid. The grid does not directly support sorting — that is, it doesn't sort the contents of the grid for you. Instead, it provides a way for you to add sort options to the grid, such as hyperlinks in the column heads that users click to sort. The grid then notifies you when a user has requested sorting. You then sort the data source and rebind the data source to the **DataGrid**.

The **DataGrid** control provides two levels of sorting support:

- **Default sorting** You specify that you want the grid to support sorting. The column headings are all link buttons; when the user clicks one, you are notified of the sort. This solution is easy, but does not allow you to pick which columns support sorting — they all do.
- **Custom sorting** You define which columns support sorting. This is a more complex option, because you must define the columns using either bound columns or template columns. However, not only does this allow you to specify which columns can be sorted, but you can use whatever control you want in the column header as the sort button. For example, you might use a graphic that you create using an **ImageButton** Web server control.

For details, see Adding Sorting to a DataGrid Web Server Control.

DataGrid Columns

When you are working with a **DataGrid** Web server control, you can build several different types of columns into the grid:

- Bound columns
- Button columns
- Hyperlink columns
- Template columns

In addition, it is also possible to allow the grid to auto-generate columns based on information in the grid's data source.

Auto-Generated Columns

If the **DataGrid** control's AutoGenerateColumn property is set to **true**, the control will generate and display a bound column for each bindable column in the data source. Bindable column types include primitive types, string, datetime, and decimal. If you have a field in your data source that is not a supported column type, then the control does not create a column for that field. As long as your data source has at least one bindable column, the **DataGrid** control binds to the source and generates the bindable columns, and ignores those that are not. If **AutoGenerateColumns** is **true** and you create explicit columns, the grid will show both your explicit columns and the auto-generated ones.

Using auto-generated columns is a quick and easy way to display information in the grid. Because these columns are automatically generated at run time and displayed in the order in which they occur in the data source, you do not have flexibility in how these columns are laid out. Therefore, using auto-generated columns is recommended primarily for simple data display, prototype pages, and other situations where you do not necessarily need to lay the columns out carefully. You should explicitly define columns when you want to control which columns to display and in what order.

Bound Columns

A bound column (BoundColumn element) displays information from one column of a data source. You typically add one bound column to the grid for every data column you want to display. Use bound columns when you want to choose which data columns to display in the grid. Bound columns also allow you to set a variety of properties to specify features such as:

- The text, font, and color of the column header and footer.
- Column width.
- Data format.
- Whether the column is read-only (that is, whether it will display an editable control when the row is in edit mode).

For details on creating bound columns in the Visual Studio Web Forms Designer, see Adding Bound Columns to a DataGrid Web Server Control. For details on creating bound columns, see DataGrid Web Server Control.

Button Columns

Button columns allow you to add grid columns with buttons that allow users to perform row-specific functions such as selecting the current row, deleting it, putting it into edit mode. You can create buttons for predefined functions or create your own functionality (for example, an "Add to Shopping Cart" button).

You can define two types of button columns:

- An EditCommandColumn element is predefined to contain three buttons. In display mode, the column displays an Edit button that users can click to put the row into edit mode (with editable controls). When the row is in edit mode, the Edit button is replaced with two buttons: an Update button and a Cancel button. You can specify the text (caption) of the buttons.
- A ButtonColumn element can contain any arbitrary button. You can use a **ButtonColumn** element to define certain predefined functionality (such as selecting a row or deleting it) or to create buttons for your own functionality.

When you define a button for a button column, you specify the button's text (caption) and its button type (LinkButton or Button). In addition, for buttons in the **ButtonColumn** element, you specify a special CommandName property. The setting for this property determines what happens when the button is clicked. For example:

Setting	Result
Select	Clicking the button automatically selects the row.
Delete	Clicking the button raises the **DataGrid** control's DeleteCommand.

A custom (non-predefined) value	Clicking the button raises the **DataGrid** control's generic ItemCommand.

Note Settings for the **CommandName** property are case sensitive.

In most cases, the button click raises an event that you then handle. (If the **CommandName** property is set to "Select," the event is raised, but it is also handled automatically by the grid to select the specified rows.) Typically, in your handler you determine which row was affected and the appropriate action — for example, setting that row into edit mode (or canceling it), deleting the data row represented by that grid row, and so on. For custom buttons, the grid raises the **ItemCommand** event and passes the value of the **CommandName** property as part of the **EventArgs** object.

For details on creating button columns in the Visual Studio Web Forms Designer, see Adding Button Columns to a DataGrid Web Server Control. For details on creating button columns, see DataGrid Web Server Control.

For implementing the functionality of button columns, see the following topics:

- Allowing Users to Edit Items in a DataGrid Web Server Control
- Allowing Users to Select Items in a DataGrid Web Server Control
- Allowing Users to Delete Items in a DataGrid Web Server Control

Hyperlink Columns

A hyperlink column (HyperLinkColumn element) displays a link in each row. You can specify static text for the hyperlink or derive the link's text from a data column. Similarly, you can specify a static URL as the link's target or get the URL from a data source.

For details on creating hyperlink columns in the Visual Studio Web Forms Designer, see Adding Hyperlink Columns to a DataGrid Web Server Control. For details on creating button columns as HTML elements, see DataGrid Web Server Control.

Template Columns

A template column allows you to create a custom layout for a column based on any mixture of controls and static text. Template columns are similar to templates used for the **DataList** and **Repeater** controls, with the difference that you are creating the layout for just a column rather than for a row-like item. For details about templates, see Web Server Controls Templates.

Because they give you complete control over the contents of the column, template columns provide the greatest flexibility for column layout. Some examples include:

- You can easily mix static text with controls.
- You can specify what controls are used in edit mode. When a bound column is in edit mode, it displays a text box no matter what type of data is being edited. By using a template control, you can specify a check box, a drop-down list, or other appropriate control instead.

Within the template column, you can create up to four separate template types:

- The HeaderTemplate and FooterTemplate define what will appear in the column header and footer, respectively.
- The ItemTemplate defines how information appears in the column when the row is in display mode. You often add controls such as a Label or Literal control to display data.
- The EditItemTemplate defines the controls (and text, if applicable) that appear in the column when it is in edit mode. Typically, this involves text boxes, check boxes, and drop-down lists.

For details on creating template columns in the Visual Studio Web Forms Designer, see Adding Template Columns to a DataGrid Web Server Control. For details on creating template columns as HTML elements, see DataGrid Web Server Control.

Adding DataGrid Web Server Controls to a Web Forms Page

You can add and configure a **DataGrid** Web server control in a few steps in order to display data on the page. In many cases, you will refine the grid to format the columns or add editing or sorting.

The following procedure describes the basic steps to create a working **DataGrid** control.

To add a DataGrid Web server control to a Web Forms page

1. Add a data source to the Web Forms page. There are several methods for handling data in a Web application. To choose an appropriate method, see Introduction to Data Access with ADO.NET and Introduction to Data Access in Web Forms Pages.
2. In Design view, drag a **DataGrid** control from the Web Forms tab of the Toolbox onto the page.
3. Set the control's **DataSource** property. In the Properties window, the drop-down list for the **DataSource** property will display all the data sources, such as **DataSet** and **DataView** controls, defined on the page.

   By default, the **DataGrid** control will generate a bound column for each field in the data source. Each field in the data source is rendered in a separate column, in the order it occurs in the data source. Field names appear in the grid's column headers, and values are rendered in text labels.

4. In code, call the control's **DataBind** method. This is typically done the first time the page runs (when `Page.IsPostBack` is false) in the page's **Page_Load** event using code as shown below. The **DataBind** method needs to be called whenever the data changes. On subsequent round trips of the page (when `Page.IsPostBack` is **true**), the **DataBind** method is typically called in the event handler, such as the paging event, **PageIndexChanged**, when the data you wish to display in the grid changes.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   'Put user code to initialize the page here
   If Not Page.IsPostBack Then
   ' Put user code here to initialize the data source
   ' (such as filling a dataset)
      DataGrid1.DataBind()
   End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   if (!Page.IsPostBack)
   {
      // Put user code here to initialize the data source
      // (such as filling a dataset)
      DataGrid1.DataBind();
   }
}
```

Adding Template Columns to a DataGrid Web Server Control

By using a template column, you can specify the controls that appear in your column. The template column supports four items — header, footer, item, and edit item. The buttons that you add to a template column bubble their click events to the **DataGrid's ItemCommand** event.

To add a template column to the DataGrid

1. Add a **DataGrid** to the page. For more information, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, on the **General** tab, select the **DataSource** and **DataMember**.

   There are several methods for handling data in a Web application. To choose an appropriate method, see Introduction to Data Access with ADO.NET and Introduction to Data Access in Web Forms Pages. If you have created a data source using a **DataSet** or **DataView** control in the designer, you will be able to pick the data control from the drop-down list for the **DataSource** property.

4. Switch to the **Columns** tab.
5. In the **Available columns** box, select **Template Column** and click the **Add** button ( ). Click **OK** to close the ***DataGrid* Properties** dialog box.
6. In the designer, right-click the **DataGrid** control, point to **Edit Template**, and choose the template column you created.
7. You can edit four templates — Header, Footer, Item, and EditItem. Add controls to the template as needed.
8. To exit edit mode, right-click the **DataGrid** control and select **End Template Editing** from the menu.
9. Add code to respond to any button-click events from buttons in the template column. For information on responding to button events in the templates, see Responding to Button Events in DataList, Repeater, or DataGrid Items.

Adding Bound Columns to a DataGrid Web Server Control

Using bound columns in a **DataGrid** Web server control allows you to specify which columns from the data source to display, customize the header and footer for each column, and control sorting.

To add bound columns to a DataGrid control

1. Add a **DataGrid** to the page. For more information, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, click the **Columns** tab.
4. Clear the **Create columns automatically at run time** check box.
5. In the **Available columns** box, expand **Data Fields** and select a field to display, then click the **Add** button ( ).
6. Optionally, set the header text and footer text for each column you add. If you want to use an image rather than text for the header, select an image in the **Header image** box.

   Note The header and footer will be displayed only if you have selected **Show header** and **Show footer** in the **General** tab.

7. If you want to be able to sort by the contents of the column, set the **Sort expression** for the column. For details, see Adding Sorting to a DataGrid Web Server Control.
8. If you want the data in the column to be formatted — for example, if you want to specify how a date is displayed — set the **Data formatting expression**. For information about creating a formatting expression, see Composite Formatting.

Adding Hyperlink Columns to a DataGrid Web Server Control | Adding Template Columns to a DataGrid Web Server Control |
DataGrid Web Server Control

Adding Button Columns to a DataGrid Web Server Control

A **ButtonColumn** column in a **DataGrid** Web server control allows you to define custom functionality for items in the grid beyond the edit, delete, select, and hyperlink features of other column types. For example, you can use a **ButtonColumn** to create an "Add to shopping cart" button.

You can specify that the buttons in the **ButtonColumn** be either **PushButton** (pushbutton-style) or **LinkButton** (hyperlink-style) buttons. The button captions can either be static text or text read from a database.

When you define a button column, you specify a command associated with the button. When users click the button, the button's command is passed to the container — the **DataGrid** control — where you can handle it with your custom code.

To add a button column

1. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
2. In the ***DataGrid* Properties** dialog box, click the **Columns** tab.
3. In the **Available columns** box, select **Button Column** and click the **Add** button (>).

   Note The **Button Column** node can be expanded to reveal the **Select**, **Edit**, and **Delete** button column types. For a custom button, however, you must select the **Button Column** node.

4. Set the column's header text and footer text. If you want to use an image rather than text for the header, select the image in the **Header image** box. By default, the **DataGrid** displays the name of the field in the data source as the header text.

   Note The header and footer will be displayed only if you have selected **Show header** and **Show footer** in the **General** tab.

5. If you want to be able to sort by the contents of the column, set the **Sort expression** for the column. For details, see Adding Sorting to a DataGrid Web Server Control.
6. If you are creating a button with static text, set the button's caption in the **Text** box. If you are displaying the contents of a database field as the caption of the button, select the field from the **Text field** list. If you are setting the button text using a text field, you can specify a formatting expression for the text using the **Text format string** box. For information about creating a formatting expression, see Composite Formatting.
7. Select whether the button is a link button (hyperlink-style) or push button from the **Button type** list.
8. In the **Command name** box, enter the command that should be sent to the **DataGrid** control when the button is clicked. For details about working with the command text, see the section below, "To respond to button events."

Defining the button column is one part of creating custom buttons in the grid. You must also create an event handler to respond when a user clicks a button.

To respond to button events

1. Create an event handler for the **DataGrid** control's ItemCommand event. This event is raised when the user clicks any button in any button column in the grid. For details, see Creating Event Handlers in Web Forms Pages.
2. In the method, you determine which button was clicked by examining the information passed in the **DataGridCommandEventArgs** argument of the event.
   a. Check the **CommandName** property of the event-argument object (`e.CommandName`) to see what command string was passed.
   b. Use the **Item** property of the argument object to get a reference to the DataGridItem Class instance associated with the row where the user clicked. The **Item** property in turn contains a **Cells** collection (`e.Item.Cells`) containing the contents of the current row. Each cell has a **Text** property containing the contents of the cell.

The following example shows how you can test to see whether the command string `"AddToCart"` was passed to the event handler. If so, the example extracts the value of a column (2) containing a product ID, which is used to add items to the shopping cart.

```
' Visual Basic
Private Sub DataGrid1_ItemCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataGridCommandEventArgs) _
Handles DataGrid1.ItemCommand
   'e.Item is the row of the table where the button was
   ' clicked.
```

```
    Dim productID As String
    productID = e.Item.Cells(2).Text
    If (e.CommandName = "AddToCart") Then
        ' Add code here to add the productID item to the cart.
    End If
    DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_ItemCommand(object source,
System.Web.UI.WebControls.DataGridCommandEventArgs e)
{
    // e.Item is the row of the table where the button was
    // clicked.
    string productID = e.Item.Cells[2].Text;

    if (e.CommandName == "AddToCart")
    {
        // Add code here to add the productID item to the cart.
    }
    DataGrid1.DataBind();
}
```

DataGrid Columns | Adding DataGrid Web Server Controls to a Web Forms Page | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control

Adding Hyperlink Columns to a DataGrid Web Server Control

A Hyperlink column allows you to display text as a hyperlink that users can click to navigate to another page. The text of the hyperlink can either be static — the same text for every item — or the contents of a field in the data source. Similarly, the target page for the hyperlink can be a single page for all the hyperlinks, or a URL derived from the data source.

> **Security Note** The URLs associated with a hyperlink can be tampered with by a malicious user. For more information, see Scripting Exploits.

To add a hyperlink column

1. Add a **DataGrid** to the page. For more information, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, click the **Columns** tab.
4. In the **Available columns** box, select **Hyperlink Column** and click the **Add** button (>).
5. Optionally, do the following:
   - Set the column's header text and footer text. If you want to use an image rather than text for the header, select an image in the **Header Image** box.

     > **Note** The header and footer will be displayed only if you have selected **Show header** and **Show footer** in the **General** tab.

   - If you want to be able to sort by the contents of the column, set the **Sort expression** for the column. For details, see Adding Sorting to a DataGrid Web Server Control.
6. Specify the text to display as a hyperlink using one of the following methods:
   - To specify static text (same text for every row in the grid), enter it into the **Text** box.
   - To create the hyperlink from the data source, select the name of the field from the **Text field** list. In this case, you can specify a formatting expression for the hyperlink text using the **Text format string** box. For more information about format expressions, see Composite Formatting.
7. Specify the target page for the hyperlink using one of the following methods:
   - To specify a static page (same target page for every item), enter it into the **URL** box.
   - Optionally, specify a target frame or window in the **Target** box.
   - To use a data field as the source for the target page URL, select the field name from the **URL field** list. In this case, you can specify a formatting expression for the hyperlink text using the **URL format string** box. For more information about format expressions, see Composite Formatting.

To pass information to the target page

You can use **URL field** to pass data to a target page.

- Enter a value for the **URL field** box specifying the data field you wish to pass and define a format for the URL in the **URL format string** that includes the target page. For example, to pass the value of the **LastName** field in the data source to a page about benefits, the **URL field** would be set to `LastName`, and the **URL format string** would be set to `Benefits.aspx?LastName={0}`.

  If you provide information in the **URL Field** box in this way, it is passed to the target page as a query string. In the target page you can get the value passed from the hyperlink by examining the contents of the **QueryString** parameter. In a Web Forms page, you can do this in the **Page_Load** event. The following example shows how you can retrieve the value passed to the target page.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   ' Add code here to initialize the page.
   Dim lastName As String = Request.QueryString("LastName")
   ' Add code here to process LastName.
```

```
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   // Add code here to initialize the page.
   string lastName = Request.QueryString["LastName"];
   // Add code here to process LastName.
}
```

DataGrid Columns | Adding DataGrid Web Server Controls to a Web Forms Page | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control

Adding Sorting to a DataGrid Web Server Control

The **DataGrid** Web server control provides a way for you to add sorting to the grid using these methods:

- **Default sorting** All columns in the grid can be sorted. The header for each column contains a **LinkButton** control (hyperlink) that users click to sort by that column.
- **Custom sorting** You define which columns can be sorted and what type of button in the column heading users click to sort.

In either case, the grid does not sort the rows. Instead, it notifies you of the sort request by raising an event. You then perform the sort in your own code, usually by sorting and then rebinding to the data source.

Specifying Default Sorting

To use default sorting, you set properties of the **DataGrid** control to enable sorting for all columns. You then create an event handler to perform the sort.

To specify default sorting

1. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
2. In the ***DataGrid* Properties** dialog box, click the **General** tab.
3. Set the grid's **AllowSorting** property to **true**.

At run-time, the headers for all columns are automatically rendered as **LinkButton** controls. When the user clicks a column head, the name of the bound field for that column is passed as the sort key.

Specifying Custom Sorting

You can define custom sorting by including bound columns and template columns in the grid and writing code in the **SortCommand** event to sort the data.

To specify custom sorting

1. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
2. In the ***DataGrid* Properties** dialog box, click the **General** tab.
3. In the **Behavior** section, select the **Allow sorting** box.
4. Switch to the **Columns** tab.
5. Add any combination of bound columns and template columns to the **DataGrid** control. For details, see Adding Bound Columns to a DataGrid Web Server Control and Adding Template Columns to a DataGrid Web Server Control.
6. To enable sorting for a column, enter a value for the **Sort expression** for that column. This can be any string value, but is typically the name of the data field to which the column is bound.

   Note Columns without a sort expression will not raise the **SortCommand** event.

7. Add an event handler for the **SortCommand** event and continue as described in the section below, "Performing the Sort." For more information on event handlers, see Creating Event Handlers in Web Forms Pages.

If you include template columns, you can specify what type of button a user clicks in the column heading to raise the **SortCommand** event.

To specify a button type for sorting in a template column

1. Select the template column to work with and enter a value for its **Sort expression**. This can be any string value, but is typically the name of the data field to which the column is bound.
2. Edit the header template for that column. For details about editing templates, see Creating Web Server Control Templates.
3. Add a **Button**, **LinkButton**, or **ImageButton** control to the template and set its properties to specify a caption or graphic.
4. Set the **Command** property of the button to **sort** (case-sensitive).
5. Add an event handler for the **SortCommand** event and continue as described in the next section, "Performing the Sort." For more information on event handlers, see Creating Event Handlers in Web Forms Pages.

Performing the Sort

When the user clicks the button or hyperlink in the header that has sorting enabled, the **SortCommand** event for the **DataGrid** is raised. In the event handler, you sort the data and rebind it to the **DataGrid**.

To respond to a sort request

- Create an event handler for the grid's SortCommand event. In the method:

  1. Get the sort key (the value you set in the **Sort expression**) from the **SortExpression** property of the **DataGridSortCommandEventArgs** argument.
  2. Sort the data.
  3. Rebind the data from the data source.

     The following example shows how to sort by handling the **SortCommand** event. The method gets the sort key value and uses it to set the **Sort** property of a **DataView** object. The code then rebinds the grid to the **DataView** object, which automatically returns the data in sorted order.

```
' Visual Basic
Private Sub DataGrid1_SortCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataGridSortCommandEventArgs) _
Handles DataGrid1.SortCommand
   DataView1.Sort = e.SortExpression
   DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_SortCommand(object source,
System.Web.UI.WebControls.DataGridSortCommandEventArgs e)
{
   dataView1.Sort = e.SortExpression;
   DataGrid1.DataBind();
}
```

Adding DataGrid Web Server Controls to a Web Forms Page | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control | Paging Behavior in DataGrid Web Server Controls

Allowing Users to Delete Items in a DataGrid Web Server Control

You can set up your **DataGrid** so that a user can delete a particular row by clicking a button. There are three ways to create a Delete button. You can:

- Have the Property Builder create the Delete button
- Create the button yourself in the Property Builder
- Add the button to a template column

In each case, you create a button control that has "Delete" as the **CommandName** property. Then you add code to the **DeleteCommand** event to delete the item from the data source.

To have the Property Builder create a Delete button

1. Add a **DataGrid** to your Web Forms page. For more information, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, click the **Columns** tab.
4. In the **Available columns** box, expand the **Button Column** item and choose **Delete**.
5. Click the **Add** button (>) to add the **Delete** column to the **Selected Columns** list.
6. The **Command name** property for the button is **Delete**. You must leave this property set to **Delete** if you want the click to raise the **DeleteCommand** event.
7. Set the rest of the button's properties as you want. For details about setting properties for button columns, see Adding Button Columns to a DataGrid Web Server Control.
8. Add code to the **DeleteCommand** event handler to delete the row from the data source and rebind the data to the **DataGrid**. See the section, "To delete the item from the data source."

To create a Delete button using the Property Builder

1. Add a **DataGrid** to your Web Forms page. For more information, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, click the **Columns** tab.
4. In the **Available columns** box, select the **Button Column** item.
5. Click the **Add** (>) button to add the **Button** column to the **Selected Columns** list.
6. Set the **Command name** property to **Delete**.
7. Set the rest of the buttons as you want. For details about setting properties for button columns, see Adding Button Columns to a DataGrid Web Server Control.
8. Add code to the **DeleteCommand** event handler to delete the row from the data source and rebind the data to the **DataGrid**. See the section below, "To delete the item from the data source."

To add a Delete button to a template column

1. Add a template column to your **DataGrid**. For information, see Adding Template Columns to a DataGrid Web Server Control.
2. In Design view, right-click the **DataGrid** and select **Edit Template**. Choose the template to which you want to add a Delete button.
3. Add a **Button**, **ImageButton**, or **LinkButton** control to the **ItemTemplate**.
4. Set the **CommandName** property of the button control to **Delete**.
5. Add code to the **DeleteCommand** event handler to delete the row from the data source and rebind the data to the **DataGrid**. See the following section, "To delete the item from the data source."

To delete the item from the data source

1. Create an event handler for the control's **DeleteCommand** event. For more information, see Creating Event Handlers in Web Forms Pages.

2. In the event handler, use the **e.Item.ItemIndex** property to identify the row to be deleted. Delete the row from the data source and rebind the data to the control. The code could look similar to the following:

```
' Visual Basic
Private Sub DataGrid1_DeleteCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataGridCommandEventArgs) _
Handles DataGrid1.DeleteCommand
   Dim index As Integer
   index = e.Item.ItemIndex
   ' Add code to delete data from data source.
   DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_DeleteCommand(object source,
System.Web.UI.WebControls.DataGridCommandEventArgs e)
{
   int rowToDelete = e.Item.ItemIndex;
   // Add code to delete row from data source.
   DataGrid1.DataBind();
}
```

Adding DataGrid Web Server Controls to a Web Forms Page | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control | Allowing Users to Select Items in a DataGrid Web Server Control

Allowing Users to Edit Items in a DataGrid Web Server Control

You can allow users to do in-place editing of information in grid rows. To do so, you create an **Edit, Update, Cancel** column using the Property Builder, and add code to the **EditCommand**, **UpdateCommand**, and **CancelCommand** events of the **DataGrid**. At run time, this column displays a button labeled "Edit". When the user clicks this Edit button, the row data is displayed in editable controls such as text boxes, and the Edit button is replaced with Update and Cancel buttons. Clicking the Update button raises the **UpdateCommand** event, where you add code to propagate the data changes back to your data source. Clicking the Cancel button raises the **CancelCommand** event, where you add code to rebind the original data to the **DataGrid**.

To add an Edit, Update, Cancel column

1. Add a **DataGrid** control to your Web Forms page. For details, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, click the **General** tab. If you want to associate data from a key field with each row in the grid, select a field name from the **Data key field** list. You can use this information to update a specific item in the data source. For example, if you set the **DataKeyField** to be **customerId**, you could later update the record using a statement such as the following:

```
' Visual Basic
Dim customerId as Integer
customerId=DataGrid1.DataKeys(DataGrid1.SelectedIndex)

// C#
int customerId;
customerId=(int)DataGrid1.DataKeys[DataGrid1.SelectedIndex];
this.Label1.Text = customerId.ToString();
```

4. Switch to the **Columns** tab and expand the **Button Column** node in the **Available columns** box.
5. Select **Edit, Update, Cancel** and click the **Add** button (>).
6. Set the header, footer, and sort information as needed. For more information, see Adding Button Columns to a DataGrid Web Server Control.
7. Use the **Edit text**, **Cancel text**, and **Update text** properties to specify the text that appears on the buttons.
8. Use the **Button type** property to specify whether the buttons are displayed as **PushButtons** or **LinkButtons**.
9. If you want the row in edit mode to have a special look, set the properties of the **EditItemStyle** object. For details, see Specifying Grid Item Format in a DataGrid Web Server Control.
10. You must create the **EditItemTemplate** for any template columns. For more information, see Adding Template Columns to a DataGrid Web Server Control.

When a user clicks a button, an event is raised on the **DataGrid** control corresponding to the button. You add code to implement the task according to the event as described in the following table:

DataGrid Event	Response
EditCommand	Put current row into edit mode by setting the **EditItemIndex** property.
UpdateCommand	Extract contents of current row and update the data source, cancel the edit mode of the row, and rebind the up dated data to the **DataGrid** control.
CancelCommand	Cancel edit mode of the row, and rebind the original data to the **DataGrid** control.

To create event handlers for Edit, Update, and Cancel events

1. Create an event handler for the control's **EditCommand** event. For more information, see Creating Event Handlers in Web Forms Pages. In the event handler, do the following:
   a. Set the **DataGrid** control's **EditItemIndex** property to the index value of the item to put into edit mode. The index of the item the user clicked is available via the **Item** property's **ItemIndex** property.
   b. Rebind the control to its data source.

   The event handler could look like this:

```
' Visual Basic
```

```
Private Sub DataGrid1_EditCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataGridCommandEventArgs) _
Handles DataGrid1.EditCommand
   DataGrid1.EditItemIndex = e.Item.ItemIndex
   DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_EditCommand(object source,
System.Web.UI.WebControls.DataGridCommandEventArgs e)
{
   DataGrid1.EditItemIndex = e.Item.ItemIndex;
   DataGrid1.DataBind();
}
```

2. Create a method for the **UpdateCommand** event that reads the values of the editing controls in the current item and writes them back to the data source.

   Security Note User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

   - Bound columns The **e.Item** property contains an indexed **Cells** collection that contains one **Cell** object for each column in the **DataGrid** control. The data is found in the first control in the **Controls** collection of the cell. The following statements retrieve the string data from the **TextBox** control displayed in the second column:

```
' Visual Basic
Dim newData As String
Dim aTextBox As TextBox
aTextBox = CType(e.Item.Cells(1).Controls(0), TextBox)
newData = aTextBox.Text

// C#
string newData;
TextBox aTextBox;
aTextBox = (TextBox)(e.Item.Cells[1].Controls[0]);
newData = aTextBox.Text;
```

   - Template columns The **e.Item** property contains an indexed **Cells** collection that contains one **Cell** for each column in the **DataGrid**. The data is contained in controls you created while editing the template. Use the **FindControl** method and the control's name to retrieve the data. The following statements retrieve the string data from the **TextBox** control with **Name** property "FirstName" in the second column:

```
' Visual Basic
Dim newName As String
Dim box As TextBox
box = CType(e.Item.Cells(1).FindControl("FirstName"), TextBox)
newName = box.text

// C#
string newName;
TextBox box;
box = (TextBox)(e.Item.Cells[1].FindControl("FirstName"));
newName = box.Text;
```

   - After updating the data source, switch the item back out of editing mode by setting the **EditItemIndex** property to -1, and then rebind to the data source. A complete example follows:

```
' Visual Basic
Private Sub DataGrid1_UpdateCommand(ByVal source As Object, _
```

```
ByVal e As System.Web.UI.WebControls.DataGridCommandEventArgs) _
Handles DataGrid1.UpdateCommand
   ' The quantity is in the 7th column.
   Dim quantityCell As TableCell = e.Item.Cells(6)

   ' The TextBox is the 0th element of the Controls collection.
   Dim quantityBox As TextBox = _
      CType(quantityCell.Controls(0), TextBox)

   ' Extract the quantity from the box.
   Dim quantity As Integer = System.Int32.Parse(quantityBox.Text)

   ' Use quantity to update the data source.

   ' Switch out of edit mode.
   DataGrid1.EditItemIndex = -1
   DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_UpdateCommand(object source,
System.Web.UI.WebControls.DataGridCommandEventArgs e)
{
   // The quantity is in the 7th column.
   TableCell quantityCell = e.Item.Cells[6];

   // The TextBox is the 0th element of the Controls collection.
   TextBox quantityBox = (TextBox)quantityCell.Controls[0];

   // Extract the quantity from the box.
   int quantity = System.Int32.Parse(quantityBox.Text);

   // Use quantity to update the data source.

   // Switch out of edit mode.
   DataGrid1.EditItemIndex = -1;
   DataGrid1.DataBind();
}
```

3. Create a method for the **CancelCommand** event that switches out of editing mode by setting **EditItemIndex** property to –1 and then rebinds to the data source:

```
' Visual Basic
Private Sub DataGrid1_CancelCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataGridCommandEventArgs) _
Handles DataGrid1.CancelCommand
   DataGrid1.EditItemIndex = -1
   DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_CancelCommand(object source,
System.Web.UI.WebControls.DataGridCommandEventArgs e)
{
   DataGrid1.EditItemIndex = -1;
   DataGrid1.DataBind();
}
```

Adding DataGrid Web Server Controls to a Web Forms Page | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control | Allowing Users to Select Items in a DataGrid Web Server Control | Allowing Users to Delete Items in a DataGrid Web Server Control

Allowing Users to Select Items in a DataGrid Web Server Control

You can set up your **DataGrid** so that a user can select a particular row by clicking a button. When a row is selected, the **SelectedIndex** property of the **DataGrid** is set to the index of the selected row, and the row is displayed using the **Selected Item** format. There are three ways to create a button control that has "Select" as the **CommandName** property. You can:

- Have the Property Builder create the Select button
- Create the button yourself in the Property Builder
- Add the button to a template column

To have the Property Builder create a Select button

1. Add a **DataGrid** to your Web Forms page. For details, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, click the **Columns** tab.
4. In the **Available columns** box, expand the **Button Column** item and choose **Select**.
5. Click the **Add** button (>) to add the **Select** column to the **Selected columns** list.
6. The **Command name** property for the button is **Select**. You must leave this property set to **Select** if you want the row to display the **Selected Item** format when the user clicks the button.
7. Set the rest of the buttons as you want. For information about setting properties for Button Columns, see Adding Button Columns to a DataGrid Web Server Control.
8. When the grid is displayed, a column with buttons labeled "Select" will appear. When the user clicks the select button, the corresponding row will be formatted using the selected item format. For more information see, Specifying Grid Item Format in a DataGrid Web Server Control.

In the previous steps, the Property Builder created a button that would allow users to select a row. In the next procedure, you use the Property Builder to create a button, but you specify the properties so that the button implements the selection behavior.

To create a Select button using the Property Builder

1. Add a **DataGrid** to your Web Forms page. For more information, see Adding DataGrid Web Server Controls to a Web Forms Page.
2. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
3. In the ***DataGrid* Properties** dialog box, click the **Columns** tab.
4. In the **Available columns** box, click Button Column.
5. Click the **Add** (>) button to add the **Button** column to the **Selected Columns** list.
6. Set the **Command name** property to **Select**.
7. Set the rest of the buttons as you want. For details about setting properties for button columns, see Adding Button Columns to a DataGrid Web Server Control.
8. When the grid is displayed, a column with buttons labeled **Select** appears. When the user clicks the select button, the corresponding row will be formatted using the selected item format. For more information see, Specifying Grid Item Format in a DataGrid Web Server Control.

To add a Select button to a template column

1. Add a template column to your **DataGrid**. For details, see Adding Template Columns to a DataGrid Web Server Control.
2. In Design view, right-click the **DataGrid**, point to **Edit Template**, and choose the template to which you want to add a Select button.
3. Add a **Button**, **ImageButton**, or **LinkButton** control to the **ItemTemplate**.
4. Set the **CommandName** property of the button control to **Select**.
5. When the grid is displayed, a column with buttons labeled "Select" will appear. When the user clicks the select button, the corresponding row will be formatted using the selected item format. For details see Specifying Grid Item Format in a DataGrid Web Server Control.

DataGrid Columns | Adding DataGrid Web Server Controls to a Web Forms Page | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control | Allowing Users to Edit Items in a DataGrid Web Server Control | Allowing Users to Delete Items in a DataGrid Web Server Control

Specifying Grid Item Format in a DataGrid Web Server Control

You can format items in the **DataGrid** Web server control to customize their appearance. You can:

- Set the color, font, borders, and spacing for the grid as a whole.
- Set the color, font, and alignment for each type of grid item (row) individually, such as item, alternating item, selected item, header, and footer. Changing these settings allows you to override the settings you make for the entire grid.
- Set the color, font, and alignment for individual columns. This is particularly useful for setting the appearance of a special-purpose column such as a button column.

> **Note** You can format the data in individual bound, button, and hyperlink columns by specifying a formatting expression. For details, see Adding Bound Columns to a DataGrid Web Server Control, Adding Button Columns to a DataGrid Web Server Control, and Adding Hyperlink Columns to a DataGrid Web Server Control. For information about creating a formatting expression, see Composite Formatting.

The formatting you set is applied in the order listed above. The grid as a whole is formatted first. If you specify an item format, that is applied next, and if you've specified a column style, that is applied last. For example, suppose you specify a format for the **Item** and **AlternatingItem** types. If you also specify a format for a column (for example, a button column) the button column format takes precedence, and the column is displayed with no difference between item and alternating item rows.

To set the format for the grid as a whole

1. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
2. In the ***DataGrid* Properties** dialog box, click the **Format** tab, and then choose **DataGrid** from the **Objects** list.
3. Choose font, color, and alignment options.

You can override the grid-wide settings for each type of item.

To set the format for an individual item

1. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
2. In the ***DataGrid* Properties** dialog box, click the **Format** tab, and under **Objects** do one of the following:
   - Select **Header**, **Footer**, or **Pager**.

     -or-

   - Expand the **Items** node and select the type of item to format.
3. Choose font, color, and alignment options for that item, and then choose **Apply**.

To set the format for an individual column

1. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
2. In the ***DataGrid* Properties** dialog box, click the **Format** tab, and under **Objects** expand the **Columns** node and select the column to format.
3. Expand the column and select whether you are formatting the column's header, footer, or content. If you do not specify formatting for a portion of the column (for example, you do not format the column's header), that portion is displayed with the defaults inherited from the grid or item.

> **Note** To remove column formatting, clear the formatting values.

Adding DataGrid Web Server Controls to a Web Forms Page | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control

Paging Behavior in DataGrid Web Server Controls

The **DataGrid** Web server control allows you to add paging to the grid using these methods:

Method	Description
Default paging and default navigation buttons	The **DataGrid** control displays navigation buttons as part of the **DataGrid** control. These controls are either Next and Previous buttons or page numbers. When the user clicks these buttons, the grid updates the current page number and raises an event so you can refresh the data.
Default paging and custom navigation controls	You enable paging and set the page size of the **DataGrid** control. Then you place navigation controls, such as Next and Previous buttons, on the Web Forms page. In the click events for these buttons, you manipulate the current page of the **DataGrid** control. The control then selects the appropriate data rows to display.
Custom paging	You provide your own navigation controls, manually set which page to display, and provide the rows for just that page. This option allows you to move any number of pages at a time, jump to a specific page, and so on.

For details on specifying paging behavior, see Specifying Paging Behavior in a DataGrid Web Server Control.

Default versus Custom Paging

The page displayed by the grid is determined by its **CurrentPageIndex** property. The default paging controls set this property automatically; if you are providing custom paging controls, you set it yourself. After the **CurrentPageIndex** is set, the grid is re-bound to the data source. The grid recreates the entire dataset and automatically moves to the appropriate place in the dataset. It then displays enough rows to make one page of the grid.

If you are working with a large dataset, recreating the entire dataset each time users navigate to a new page can degrade performance. By using custom paging, you can retrieve data in page-size "chunks" — that is, retrieve just a page worth of records at a time. To do that, you turn off the automatic paging feature of the grid so that it doesn't assume that it is working with the entire dataset. You then get the correct number of rows to fill the grid. For information on implementing custom paging, see DataGrid.AllowCustomPaging Property.

Specifying Paging Behavior in a DataGrid Web Server Control | DataGrid Web Server Control | Introduction to the DataGrid Web Server Control

Specifying Paging Behavior in a DataGrid Web Server Control

The **DataGrid** supports three types of paging:

- Default paging with default navigation buttons
- Default paging with custom navigation controls
- Custom paging

For a discussion of these options, see Paging Behavior in DataGrid Web Server Controls.

Using Default Paging with Default Navigation Controls

To enable default paging, use the **Property Builder** to set properties to enable paging, set the page size, and specify the style of the paging controls. Paging controls are **LinkButton** controls. You can choose from these types:

- Next and previous buttons. The button captions can be any text you want.
- Page numbers, which allow users to jump to a specific page. You can specify how many numbers are displayed; if there are more pages, an ellipsis (...) is displayed next to the numbers.

You must also create an event handler that responds when users click a navigation control.

To specify paging using the Property Builder

1. In Design view, select the **DataGrid** control, then click the **Property Builder** link at the bottom of the Properties window.
2. In the ***DataGrid* Properties** dialog box, click the **Paging** tab.
3. Select the **Allow paging** box. A complete set of default paging properties is enabled.
4. Set the **Page size** property to the number of items to show on each page.
5. In the Mode list, choose to display either **Next, Previous buttons** or buttons with **Page numbers**.

   - To display "Next" and "Previous" on the navigation buttons, set the **Next page button text** and **Previous page button text** properties. The default text on the button is ">" for the next button and "<" for previous button. At run-time, the symbols "**<**" and "**>**" are displayed.

     -or-

   - Set the **Numeric buttons** property to the number of pages to be displayed. For example, if you set **Numeric buttons** to 2 (that is, display two page numbers at a time), then the user may select from pages "...", 3, 4, and "..." when page 3 is displayed.
   - If you are using page numbers, set the **PagerStyle** object's **PageButtonCount** property to the number of buttons to display.

Each of the settings in the above procedure, "To specify paging using the Property Builder", corresponds to a property of the **DataGrid**. These properties may be set in the **Page_Load** event.

To specify paging programmatically

1. Use the **Page_Load** event to enable paging and set the mode and button properties. The following example shows how you can set a **DataGrid** control called **DataGrid1** to use simple paging and respond to a navigation request. The code sets the pager style to display five numbers at a time when the page is first displayed. When users click a navigation control, the code simply rebinds to the data source.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   'Put user code to initialize the page here

   With DataGrid1
      ' Enable paging.
      .AllowPaging = True
      ' Display 5 page numbers at a time.
      .PagerStyle.Mode = PagerMode.NumericPages
      .PagerStyle.PageButtonCount = 5
```

```
        .PageSize = 5
    End With

    If Not Page.IsPostBack Then
        DataGrid1.DataBind()
    End If
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
    // Put user code to initialize the page here
    DataGrid1.AllowPaging = true;
    DataGrid1.PagerStyle.Mode = PagerMode.NumericPages;
    DataGrid1.PagerStyle.PageButtonCount = 5;
    DataGrid1.PageSize = 5;

    if (!Page.IsPostBack)
    {
        DataGrid1.DataBind();
    }
}
```

2. Create an event handler for the grid's **PageIndexChanged** event to respond to a paging request. Use the **e.NewPageIndex** to update the **DataGrid**'s **CurrentPageIndex**, then rebind the data.

```
' Visual Basic
Private Sub DataGrid1_PageIndexChanged(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataGridPageChangedEventArgs) _
Handles DataGrid1.PageIndexChanged
    DataGrid1.CurrentPageIndex = e.NewPageIndex
    DataGrid1.DataBind()
End Sub

// C#
private void DataGrid1_PageIndexChanged(object source,
System.Web.UI.WebControls.DataGridPageChangedEventArgs e)
{
    DataGrid1.CurrentPageIndex = e.NewPageIndex;
    DataGrid1.DataBind();
}
```

Using Default Paging with Custom Navigation Controls

One of the options on the **Pager** tab of the **Property Builder** is **Show navigation buttons**. If this option is not selected, no navigation controls are displayed. In this case, you can provide your own navigation buttons and manipulate the **CurrentPageIndex** property of the **DataGrid**. The **DataGrid** will still take care of breaking the data source into appropriate pages and displaying the selected page.

To provide custom navigation controls

1. Add server controls to the Web Forms page that the user can use to navigate. For example, you may want to create **ImageButton** controls with forward and reverse images on them.
2. In event handlers for your navigation controls, set the **DataGrid** control's **CurrentPageIndex** property to the page to go to, and then rebind the grid to the data source.

   The following code shows how you can create code for a VCR-style navigation panel containing buttons that allow the user to go to the first, last, previous, or next page. The buttons are defined as **Button** controls whose **CommandName** property is set to indicate the navigation direction. All four buttons call the **NavigationButtonClicked** method when they are clicked.

Note In Visual C#, you can use the integrated development environment (IDE) to hook up the events and eliminate the
`+=`
assignments shown below. In this case, create the **NavigationButtonClick** method in the Code Editor. Return to the designer. Selecting each button in turn, select the **Events** tab in the Properties window. Select the **NavigationButtonClick** event from the drop-down list in the **Click** event.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   'Put user code to initialize the page here
   If Not Page.IsPostBack Then
      DataGrid1.DataBind()
   End If
End Sub

Private Sub NavigationButtonClicked(ByVal sender As Object, _
ByVal e As EventArgs) Handles FirstPage.Click, PreviousPage.Click, NextPage.Click, LastPa
ge.Click
   Dim direction As String = CType(sender, Button).CommandName

   Select Case direction.ToUpper()
      Case "FIRST"
         DataGrid1.CurrentPageIndex = 0
      Case "PREVIOUS"
         DataGrid1.CurrentPageIndex = _
            Math.Max(0, DataGrid1.CurrentPageIndex - 1)
      Case "NEXT"
          DataGrid1.CurrentPageIndex = _
             Math.Min(DataGrid1.PageCount - 1, _
             DataGrid1.CurrentPageIndex + 1)
      Case "LAST"
         DataGrid1.CurrentPageIndex = _
             DataGrid1.PageCount - 1
      Case Else
   End Select

   DataGrid1.DataBind()
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   // Put user code to initialize the page here.

   // Have all the buttons hook up to the same event.
   First.Click += new System.EventHandler(this.NavigationButtonClick);
   Previous.Click +=
      new System.EventHandler(this.NavigationButtonClick);
   Next.Click += new System.EventHandler(this.NavigationButtonClick);
   Last.Click += new System.EventHandler(this.NavigationButtonClick);
}

private void NavigationButtonClick(object sender, System.EventArgs e)
{
   string direction = ((Button)sender).CommandName;

   switch (direction.ToUpper())
   {
```

```
        case "FIRST" :
           DataGrid1.CurrentPageIndex = 0;
           break;
        case "PREVIOUS" :
           DataGrid1.CurrentPageIndex =
              Math.Max(DataGrid1.CurrentPageIndex -1, 0);
           break;
        case "NEXT" :
           DataGrid1.CurrentPageIndex =
              Math.Min(DataGrid1.CurrentPageIndex + 1,
              DataGrid1.PageCount - 1);
           break;
        case "LAST" :
           DataGrid1.CurrentPageIndex = DataGrid1.PageCount - 1;
           break;
        default :
           break;
     }
     DataGrid1.DataBind();
  }
```

Creating Custom Paging

By using the **AllowCustomPaging** property of the **DataGrid**, you can have complete control over which records are displayed. Custom paging improves performance by reducing the amount of data moved around in the system, since you can retrieve just one page of data at a time from the data source. For information on custom paging, see DataGrid.AllowCustomPaging Property. For an example, see Walkthrough: Creating Paged Data Access Using a Web Forms Page.

Creating Templates Programmatically in the DataGrid Control

A **DataGrid** control can contain template columns in which you lay out the column by adding controls and literal text. Template columns provide you with substantially more flexibility than do bound columns, button columns, and hyperlink columns. As with templates for the **DataList** and **Repeater** controls, you can dynamically create templates for the **DataGrid** control. This allows you to define the contents, layout, and data of a column at run time.

> **Note** The procedures for working with a dynamic template column are similar to working with a dynamic template in a **Repeater** or **DataList** control. For general information on creating dynamic templates, see Creating Web Server Control Templates Dynamically.

The following are the differences between using a dynamic template in a **DataGrid** control and in the **Repeater** or **DataList** controls:

- You do not create item templates for the grid itself; instead, you create them for a column in the grid.
- There are slightly different templates for a **DataGrid** column than for a **Repeater** or **DataList** control. A **DataGrid** column does not include an alternating item or separator template. However, like the **DataList** control, it does include an **EditItem** template.

To create a dynamic template column

1. Create a template class that implements the **ITemplate** interface of the System.Web.UI namespace. For details, see Creating Web Server Control Templates Dynamically.
2. Optionally, pass into the class's constructor a value that the class can use to determine what type of template to create (**ItemTemplate**, **EditItemTemplate**, and so on).

   Typically, the template type is passed using a value from the **ListItemType** enumeration already defined in the **DataGrid** control.

3. In the class, implement the **InstantiateIn** method (the only member of the **ITemplate** interface). This method provides a way to insert an instance of text and controls into the specified container.

   The following example shows a template class for a dynamic template column. The constructor accepts two parameters: the first parameter specifies the template type to create and the second parameter allows you to pass in the name of the column you are creating. Because this is a template for a DataGrid control, the class includes code to create an **EditItem** template containing a **Textbox** control.

```
' Visual Basic
Private Class DataGridTemplate
   Implements ITemplate
   Dim templateType As ListItemType
   Dim columnName As String

   Sub New(ByVal type As ListItemType, ByVal ColName As String)
      templateType = type
      columnName = ColName
   End Sub

   Sub InstantiateIn(ByVal container As Control) _
      Implements ITemplate.InstantiateIn
      Dim lc As New Literal()
      Select Case templateType
         Case ListItemType.Header
            lc.Text = "<B>" & columnName & "</B>"
            container.Controls.Add(lc)
         Case ListItemType.Item
            lc.Text = "Item " & columnName
            container.Controls.Add(lc)
         Case ListItemType.EditItem
            Dim tb As New TextBox()
            tb.Text = ""
```

```
            container.Controls.Add(tb)
         Case ListItemType.Footer
            lc.Text = "<I>Footer</I>"
            container.Controls.Add(lc)
      End Select
   End Sub
End Class

// C#
public class DataGridTemplate : ITemplate
{
   ListItemType templateType;
   string columnName;

   public DataGridTemplate(ListItemType type, string colname)
   {
      templateType = type;
      columnName = colname;
   }

   public void InstantiateIn(System.Web.UI.Control container)
   {
      Literal lc = new Literal();
      switch(templateType)
      {
         case ListItemType.Header:
            lc.Text = "<B>" + columnName + "</B>";
            container.Controls.Add(lc);
            break;
         case ListItemType.Item:
            lc.Text = "Item " + columnName;
            container.Controls.Add(lc);
            break;
         case ListItemType.EditItem:
            TextBox tb = new TextBox();
            tb.Text = "";
            container.Controls.Add(tb);
            break;
         case ListItemType.Footer:
            lc.Text = "<I>" + columnName + "</I>";
            container.Controls.Add(lc);
            break;
      }
   }
}
```

After you have created the class for a dynamic template column, you can use it to assign columns to the **DataGrid** control at run time.

To use dynamic template columns

1. Create an instance of the TemplateColumn class.
2. Create an instance of your dynamic template, passing it an item type value if appropriate.
3. Assign the instance to one of the template properties of the **TemplateColumn** object you created in Step 1, such as **ItemTemplate**, **EditItemTemplate**, **HeaderTemplate**, and so on.

   The following example shows how to use the dynamic template column to add two columns to the **DataGrid** control. In this example, the templates are instantiated during the page load and before the control is bound to its data source.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles MyBase.Load
   Dim tc1 As New TemplateColumn()
   tc1.HeaderTemplate = New _
      DataGridTemplate(ListItemType.Header, "Column1")
   tc1.ItemTemplate = New DataGridTemplate(ListItemType.Item, _
      "Column1")
   tc1.EditItemTemplate = New _
      DataGridTemplate(ListItemType.EditItem, "Column1")
   tc1.FooterTemplate = New _
      DataGridTemplate(ListItemType.Footer, "Column1")
   DataGrid1.Columns.Add(tc1)

   Dim tc2 As New TemplateColumn()
   tc2.HeaderTemplate = New _
      DataGridTemplate(ListItemType.Header, "Column2")
   tc2.ItemTemplate = New _
      DataGridTemplate(ListItemType.Item, "Column2")
   tc2.EditItemTemplate = New _
      DataGridTemplate(ListItemType.EditItem, "Column2")
   tc2.FooterTemplate = New _
      DataGridTemplate(ListItemType.Footer, "Column2")
   DataGrid1.Columns.Add(tc2)
   SqlDataAdapter1.Fill(DsCategories1)
   DataGrid1.DataBind()
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   TemplateColumn tc1 = new TemplateColumn();
   tc1.HeaderTemplate = new
      DataGridTemplate(ListItemType.Header, "Column1");
   tc1.ItemTemplate = new
      DataGridTemplate(ListItemType.Item, "Column1");
   tc1.EditItemTemplate = new
      DataGridTemplate(ListItemType.EditItem, "Column1");
   tc1.FooterTemplate = new
      DataGridTemplate(ListItemType.Footer, "Column1");
   DataGrid1.Columns.Add(tc1);

   TemplateColumn tc2 = new TemplateColumn();
   tc2.ItemTemplate = new
      DataGridTemplate(ListItemType.Item, "Column2");
   tc2.HeaderTemplate = new
      DataGridTemplate(ListItemType.Header, "Column2");
   tc2.EditItemTemplate = new
      DataGridTemplate(ListItemType.EditItem, "Column2");
   tc2.FooterTemplate = new
      DataGridTemplate(ListItemType.Footer, "Column2");
   DataGrid1.Columns.Add(tc2);
   sqlDataAdapter1.Fill(dsCategories1);
   DataGrid1.DataBind();
}
```

DataList Web Server Control

The **DataList** Web server control displays rows of database information in customizable format. The format in which the data is displayed is defined in item, alternating item, selected item, and edit item templates. Header, footer, and separator templates are also available to let you customize the overall appearance of the **DataList**. By including **Button** Web server controls in the templates, you can connect the list items to code that allows users to switch between display, selection, and editing modes.

The following topics provide information that you will find useful in learning to work with the **DataList** control.

Provides information on specifying CSS styles in Web server controls.

Introduction to the DataList Web Server Control

The DataList Web server control displays data in a format that you can define using templates and styles. The **DataList** control is useful for displaying rows of data. Optionally, you can configure the **DataList** control to allow users to edit or delete information. You can also customize the control to support other functionality such as selecting rows.

> **Note** To precisely control the HTML used to render the list, use the **Repeater** Web server control. If you want to include paging and sorting automatically, use the **DataGrid** Web server control. For more information, see Controls for Displaying Lists On Web Pages.

The **DataList** control displays rows of data as items in the list. You use templates to define the layout of the items by including HTML text and controls. For example, you might use a **Label** Web server control in an item to display a field from the data source.

The following sections introduce you to the features of the **DataList** control.

Binding Data to the Control

The **DataList** control must be bound to a data source. Typical data sources for the **DataList** are datasets and data readers (OleDbDataReader or SqlDataReader objects). You can use data sources that you can add to your page from the Toolbox, such as the **DataSet** or DataView class. You can also bind to data sources created in code, such as a data reader or an array. The control can use as a data source any class that supports the IEnumerable interface.

When data binding, you specify a data source for the **DataList** control as a whole. When you add other controls to this control — for example, labels or text boxes in list items — you in turn bind them to the container, namely the **DataList** control.

For more information, see Data Access in Web Forms Pages.

Templates for Control Layout

In the **DataList** control, you define the layout of your information using templates.

> **Note** For an overview of using templates, see Web Server Controls Templates.

The **DataList** control supports the following templates:

Template	Description
ItemTemplate	The HTML elements and controls to render once for each row in the data source.
AlternatingItemTemplate	Like the **ItemTemplate** element, but rendered for every other row in the **DataList** control. If you use this template, you typically create a different look for it, such as a different background color than that of the **ItemTemplate**.
SelectedItemTemplate	The elements to render when the user selects an item in the **DataList** control. Typical uses are to visually mark the row using a background or font color. You can also expand the item by displaying additional fields from the data source.
EditItemTemplate	The layout of an item when it is in edit mode. This template typically contains editing controls, such as **TextBox** controls.
HeaderTemplate and **FooterTemplate**	The text and controls to render at the beginning and end of the list.
SeparatorTemplate	The elements to render between each item. A typical example might be a line (using an <HR> element).

Styles

To specify the appearance of items in a template, you can set the template's style. For example, you might specify that:

- Items are rendered with black text on a white background
- Alternating items are rendered with black text on a light gray background
- The selected item is rendered with bold black text on a yellow background
- Items being edited are rendered with black text on a light blue background

Each template supports its own style object whose properties you can set both at design time and at run time.

For an overview, see ASP.NET Server Controls and CSS Styles.

Item Layout

Not only can you use templates to specify the layout of controls and text within individual items, but you can specify how the items are laid out with respect to one another. The **DataList** control offers these options:

Option	Description
Flow versus table	In flow layout, list items are rendered inline, in the fashion of a word-processing document. In table layout, the items are rendered into an HTML table, which gives you more facilities for specifying the look of items, because it allows you to set table cell properties such as gridlines. For details see Specifying Flow or Table Format in a DataList Web Server Control.
Vertical versus horizontal ordering	By default, items in a **DataList** control are displayed in a single vertical column. However, you can specify that the control contain more than one column. If so, you can further specify whether the items are ordered vertically (like newspaper columns) or horizontally (like days in a calendar). For details see Specifying Horizontal or Vertical Layout in a DataList Web Server Control.
Number of columns	Regardless of whether items in a **DataList** control are ordered vertically or horizontally, you can specify how many columns the list will have. This permits you to control the rendered width of the Web page, usually so that horizontal scrolling may be avoided.

Events

The **DataList** control supports several events. One of them, the **ItemCreated** event, gives you a way to customize the item-creation process at run-time. The **ItemDataBound** event also gives you the ability to customize the **DataList** control, but after the data is available for inspection. For example, if you were using the **DataList** control to display a to-do list, you could display overdue items in red text, completed items in black text, and other tasks in green text. Either event may be used to override formatting from the template definition.

The remaining events are raised in response to button clicks in list items. They are designed to help you respond to the most commonly used functionality for the **DataList** control. Four events of this type are supported:

- **EditCommand**
- **DeleteCommand**
- **UpdateCommand**
- **CancelCommand**

When a user clicks a button in an item, the event bubbles to the button's container — the **DataList** control. The exact event that the button raises depends on the **CommandName** property of the button that was clicked. For example, if the **CommandName** property of a button is **edit**, the button causes an **EditCommand** event to be raised. If the **CommandName** property is **delete**, the button causes a **DeleteCommand** event to be raised, and so on.

The **DataList** control also supports the **ItemCommand** event that is raised when a user clicks a button that doesn't have a predefined command such as **edit** or **delete**. You can use this event for custom functionality by setting a button's **CommandName** property to a value you need and then testing for it in the **ItemCommand** event handler. (For example, you could use this approach when selecting an item, as documented in Allowing Users to Select Items in a DataList Web Server Control.)

For a complete list of the events supported by the **DataList** control, see DataList Events. For more information about Web Forms events, see ASP.NET Server Control Event Model.

Editing and Selecting Items

You can allow users to edit individual items in the control. The general strategy is to create an **EditItemTemplate** that provides the appropriate layout and controls for editing. You must also provide a way for users to indicate that they want to edit the item. The most common way is to include a button in the item template (and **AlternatingItemTemplate**, if you are using that) and set the button's **CommandName** property to **edit**. Then when the button is clicked, the **DataList** control automatically raises the **EditCommand** event. In the event handler for that event, you set the item to edit mode, which displays the **EditItemTemplate**.

The **EditItemTemplate** usually includes buttons to allow the user to save the changes or discard them (for example, Update and Cancel buttons). These buttons work similarly to the Edit button — they send a predefined command message (**update** or **cancel**) to the **DataList** control, which raises an **UpdateCommand** or **CancelCommand** event that you can respond to appropriately. For a customer tracking application, the templates might appear as in the following figure.

The process for selecting an item is similar, using the **SelectedIndexChanged** event. Your add a button to the Item template and sets its **CommandName** property to **select**. You then write an event handler for the **SelectedIndexChanged** event. The

SelectedIndexChanged event is raised when the user clicks the Select button. For details see Allowing Users to Select Items in a DataList Web Server Control.

The DataList in Edit Template Mode

Adding DataList Controls to a Web Forms Page

To add a **DataList** Web server control to a page requires several steps. The following procedure describes the minimum that you must do to create a working **DataList** control.

To add a DataList Web server control to a Web Forms page

1. Add a data source to the Web Forms page. There are several methods for handling data in a Web application. To choose an appropriate method, see Introduction to Data Access with ADO.NET and Introduction to Data Access in Web Forms Pages.
2. In Design view, drag a **DataList** control from the **Web Forms** tab of the Toolbox onto the page.
3. Set the control's **DataSource** property. In the Properties window, the drop-down list for the **DataSource** property will display all the data sources, such as **DataSet** and **DataView** controls, defined on the page.
4. In Design view, right-click the **DataList** control, point to **Edit Template**, then click **Item Templates**. The control is displayed in template-editing mode.

   Note For background information about using templates, see Web Server Controls Templates.

5. Add HTML text and other controls (Web server controls or HTML server controls) to the **ItemTemplate**. For details on editing templates, see Creating Web Server Control Templates.

   Note You must add some data-bound content to one of the item templates in order for the **DataList** control to render when the page is browsed.

6. Optionally, define an **AlternatingItemTemplate**, **SelectedItemTemplate**, and **EditItemTemplate**.
7. When you are through editing templates, right-click the **DataList** control and choose **End Template Editing**.

Allowing Users to Delete Items in a DataList Web Server Control

You can allow users to delete items in a **DataList** control in a variety of ways. One way is to include a Delete button in an item and to delete that item immediately when the user clicks it.

Another way is to include a check box in individual items. Users can then check all the items they want to remove and then click a separate Delete button to delete them in a batch. This method is used in programs such as MSN Hotmail.

To allow users to delete individual items

1. In the **ItemTemplate** (and **AlternatingItemTemplate**, if you are using it), add a **Button** or **LinkButton** Web server control. Set the **CommandName** property for this button to **delete** (case-sensitive).
2. Create an event handler for the **DeleteCommand** event. For details, see Creating Event Handlers in Web Forms Pages. In the method:
   a. Delete the item from the data source and then rebind the **DataList** control. The index of the item the user clicked is available via the **Item** object's **ItemIndex** property. To get the value of individual controls, use the **FindControl** method of the **Item** event-argument object.
   b. Rebind the control to its data source.

   The event handler might look like this, if the data source were a **DataTable** object:

```
' Visual Basic
Private Sub DataList1_DeleteCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataListCommandEventArgs) _
Handles DataList1.DeleteCommand
   ' Code to delete the item from the data source.
   Dim aTable As DataTable
   aTable = CType(DataList1.DataSource, DataTable)
   aTable.Rows(e.Item.ItemIndex).Delete()
   ' Bind the data after item is deleted.
   DataList1.DataBind()
End Sub

// C#
private void DataList1_DeleteCommand(object source,
System.Web.UI.WebControls.DataListCommandEventArgs e)
{
   // Code to delete the item from the data source.
   DataTable aTable = (DataTable)DataList1.DataSource;
   aTable.Rows[e.Item.ItemIndex].Delete();
   // Bind the data after the item is deleted.
   DataList1.DataBind();
}
```

To allow users to delete multiple items at once

1. In the **ItemTemplate** (and **AlternatingItemTemplate**, if you are using that), add a **CheckBox** Web server control and set its **ID** property to "Delete". Make sure that the **AutoPostBack** property of the **CheckBox** control is **false**. Turn off template editing by right-clicking the **DataList** control and selecting **End Template Editing** from the menu.
2. Add a **Button** Web server control to the Web Forms page. Set the **Text** property to **Delete All** and the ID property to **DeleteAll**. This button is not added to one of the **DataList** templates.
3. Create a method for the **Click** event of the **Delete All** button. In the method:
   a. Loop through the **Items** collection of the **DataList** control, extracting each item in turn.
   b. Within the item, use the item's **FindControl** method to get the **CheckBox** control from Step 1 and test its **Checked** property.
   c. If the box is checked, delete the corresponding item from the data source.

d. Rebind the **DataList** control to its data source.

The following example shows an event handler for the **DeleteAll** button that deletes items in a batch using the procedure outlined above.

```
' Visual Basic
Private Sub DeleteAll_Click(ByVal sender As Object, _
ByVal e As System.EventArgs) Handles DeleteAll.Click
   Dim isDeleted As Boolean
   Dim anItem As DataListItem

   ' Check each box and see if the item should be deleted.
   For Each anItem In DataList1.Items
      isDeleted = CType(anItem.FindControl("Delete"), CheckBox).Checked
      If isDeleted Then
         ' Add code here to delete the item, using anItem.ItemIndex.
      End If
   Next
   DataList1.DataBind()
End Sub

// C#
protected void DeleteAll_Click(object sender, System.EventArgs e)
{
   bool isDeleted;

   // Check each box and see if the item should be deleted.
   foreach (DataListItem anItem in DataList1.Items)
   {
      isDeleted =
         ((CheckBox)anItem.FindControl("Delete")).Checked;
      if (isDeleted)
      {
         // Add code here to delete the item, using anItem.ItemIndex.
      }
   }
   DataList1.DataBind();
}
```

Allowing Users to Edit Items in a DataList Web Server Control

You can allow users to edit individual items in the **DataList** Web server control. When an individual item is put into edit mode, its editable values are usually displayed in text boxes or other controls that the user can change values in.

To allow users to edit items in a DataList control

1. Create an **ItemTemplate** (and **AlternatingItemTemplate**, if you are using that) and add a **Button** Web server control to it. Set the **CommandName** property for this button to **edit** (case-sensitive). For details see Creating Web Server Control Templates.

   Note You can use a **LinkButton** or an **ImageButton** in any step that calls for a **Button**.

2. Create an **EditItemTemplate** for the **DataList** control that includes the following:

   - Controls for all the values that the user can change. For example, include **TextBox** controls for all character and numeric data. Use the **DataBinding** property to set the data source for these controls. For information, see Data Access in Web Forms Pages.
   - A **Button** control with the **Text** property "Update" whose **CommandName** property is set to **update** (case-sensitive).
   - A **Button** control with the **Text** property "Cancel" whose **CommandName** property is set to **cancel** (case-sensitive).

   The Update button will allow users to specify that they are finished editing. The Cancel button will allow them to quit editing without saving changes.

3. Create an event handler for the control's **EditCommand** event. For details, see Creating Event Handlers in Web Forms Pages. In the event handler, do the following:
   a. Set the **DataList** control's **EditItemIndex** property to the index value of the item to put into edit mode. The index of the item the user clicked is available via the **Item** object's **ItemIndex** property.
   b. Bind the control to its data source.

   The event handler might look like the following:

```
' Visual Basic
Private Sub DataList1_EditCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataListCommandEventArgs) _
Handles DataList1.EditCommand
   DataList1.EditItemIndex = e.Item.ItemIndex
   DataList1.DataBind()
End Sub

// C#
private void DataList1_EditCommand(object source,
System.Web.UI.WebControls.DataListCommandEventArgs e)
{
   DataList1.EditItemIndex = e.Item.ItemIndex;
   DataList1.DataBind();
}
```

4. Create a method for the **UpdateCommand** event that reads the values of the editing controls in the current item and writes them back to the data source. To get the value of a specific control in the item, use the Control.FindControl method of the **Item** event-argument object. After updating the data source, switch the item out of editing mode by setting the **EditItemIndex** property to -1, and then rebind to the data source.

   Security Note User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

```
' Visual Basic
Private Sub DataList1_UpdateCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataListCommandEventArgs) _
```

```
Handles DataList1.UpdateCommand
   Dim quantity As TextBox
   quantity = CType(e.Item.FindControl("quantity"), TextBox)
   Dim newQuantity As String = quantity.Text
   ' Add code here to update the Quantity value of the data source
   ' using the newQuantity variable. Note that newQuantity is a
   ' string and would have to be converted to a number.
   DataList1.EditItemIndex = -1
   DataList1.DataBind()
End Sub

// C#
private void DataList1_UpdateCommand(object source,
System.Web.UI.WebControls.DataListCommandEventArgs e)
{
   TextBox quantity;
   quantity = (TextBox)(e.Item.FindControl("Quantity"));
   string newQuantity = quantity.Text;
   // Add code here to update the Quantity value of the data source
   // using the newQuantity variable. Note taht newQuantity is a
   // string and would have to be converted to a number.
   DataList1.EditItemIndex = -1;
   DataList1.DataBind();
}
```

5. Create a method for the **CancelCommand** event that sets the **EditItemIndex** property to -1 and then rebinds to the data source:

```
' Visual Basic
Private Sub DataList1_CancelCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataListCommandEventArgs) _
Handles DataList1.CancelCommand
   ' Switch out of edit mode.
   DataList1.EditItemIndex = -1
   DataList1.DataBind()
End Sub

// C#
private void DataList1_CancelCommand(object source,
System.Web.UI.WebControls.DataListCommandEventArgs e)
{
   // Switch out of edit mode.
   DataList1.EditItemIndex = -1;
   DataList1.DataBind();
}
```

Introduction to the DataList Web Server Control | Allowing Users to Delete Items in a DataList Web Server Control | Allowing Users to Select Items in a DataList Web Server Control | Creating Event Handlers in Web Forms Pages | Responding to Button Events in DataList, Repeater, or DataGrid Items

Allowing Users to Select Items in a DataList Web Server Control

You can specify that users can select individual items in the **DataList** Web server control. Typically, selecting an item highlights it visually. In addition, you might display different information for a selected item.

To allow users to select items in a DataList control

1. Set the control's **SelectedItemStyle** properties. For details, see Customizing the Appearance of ASP.NET Server Controls Using Styles.
2. Optionally, create a **SelectedItemTemplate** to display different text and controls for the selected item. For details, see Creating Web Server Control Templates.
3. In the **ItemTemplate** (and **AlternatingItemTemplate**, if you are using it), add a **Button** or **LinkButton** Web server control.
4. Set the **CommandName** property of the button from Step 3 to **select** (case-sensitive).
5. If you have created a separate **SelectedItemTemplate**, you need to rebind the list upon selection. Create an event handler for the control's **SelectedIndexChanged** event. For details, see Creating Event Handlers in Web Forms Pages. In the event handler, call the control's **DataBind** method to refresh the information in the control. The complete code would look something like this:

```
' Visual Basic
Private Sub DataList1_SelectedIndexChanged( _
ByVal sender As System.Object, ByVal e As System.EventArgs) _
Handles DataList1.SelectedIndexChanged
   DataList1.DataBind()
End Sub

// C#
private void DataList1_SelectedIndexChanged (object sender, System.EventArgs e)
{
   DataList1.DataBind();
}
```

6. To cancel the selection, set the control's **SelectedIndex** property to -1. To accomplish this, you could add a **Button** Web server control to the **SelectedItem** template and set its **CommandName** property to **unselect**. The **Click** event for this button would also be bubbled to the **DataGrid** control's **ItemCommand** event. The complete code might look something like the following:

```
' Visual Basic
Private Sub DataList1_ItemCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataListCommandEventArgs) _
Handles DataList1.ItemCommand
   If e.CommandName = "unselect" Then
      DataList1.SelectedIndex = -1
   End If
   DataList1.DataBind()
End Sub

// C#
private void DataList1_ItemCommand(object source, System.Web.UI.WebControls.DataListComma
ndEventArgs e)
{
   if (e.CommandName == "unselect")
   {
      DataList1.SelectedIndex = -1;
   }
   DataList1.DataBind();
}
```

Creating Templates Dynamically in a DataList Web Server Control

Templates do not have to be assigned at design time. In some situations, you might be able to lay out the template at design time, but changes you know you will make during run time are so extensive that loading a new template at run time simplifies the programming. In other cases, you may have several possible templates, but want to change the template at run-time.

One strategy is to create a template file with the basic template layout in it — a template definition file. To load a template at run time, use the **Page.LoadTemplate** method. This method reads a template definition from a file and creates an ITemplate Interface object. You can then assign this object to any of the templates in a **DataList**.

To create a template definition file

1. On the **Project** menu, click **Add New Item**.
2. In the **Add New Item** dialog box, select **Text File**. Name the file with the ".ascx" extension.
3. Add template definition statements to the template file and save it.

   The following listing creates a template that displays the string "Name:" followed by the "LastName" field of the data source that is bound to the **DataList**.

```
<!-- Visual Basic -->
<%@ Language = "VB" %>
Name: <b> <%# DataBinder.Eval(Container, "DataItem.LastName") %> </b>

<!-- Visual C# -->
<%@ Language = "C#" %>
Name: <b> <%# DataBinder.Eval(Container, "DataItem.LastName") %> </b>
```

To create templates dynamically

- Add code to your Web Forms page to load the template using the **Page.LoadTemplate** method.

  The following code uses the **Page_Load** event handler to load a template created as shown above and named NewTemplate.ascx.

```
' Visual Basic
Private Function CreateDataSource() As DataTable
   Dim dt As DataTable = New DataTable()
   dt.Columns.Add("LastName", Type.GetType("System.String"))
   dt.Rows.Add(New Object() {"Smith"})
   dt.Rows.Add(New Object() {"Jones"})
   dt.Rows.Add(New Object() {"Clark"})
   Return dt
End Function

Protected Sub Page_Init(ByVal Sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Init
   InitializeComponent()
   If (Not Page.IsPostBack) Then
      DataList1.AlternatingItemTemplate = _
      Page.LoadTemplate("NewTemplate.ascx")
   End If
End Sub

Private Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   'Put user code to initialize the page here
   If (Not Page.IsPostBack) Then
      DataList1.DataSource = CreateDataSource()
```

```
      DataList1.DataBind()
   End If
End Sub

// C#
private DataTable CreateDataSource()
{
   DataTable dt = new DataTable();
   dt.Columns.Add("LastName", Type.GetType("System.String"));
   dt.Rows.Add(new object[] {"Smith"});
   dt.Rows.Add(new object[] {"Jones"});
   dt.Rows.Add(new object[] {"Clark"});
   return dt;
}

private void Page_Init(object sender, EventArgs e)
{
   InitializeComponent();
   DataList1.AlternatingItemTemplate =
   Page.LoadTemplate("NewTemplate.ascx");
}

private void Page_Load(object sender, System.EventArgs e)
{
   // Put user code to initialize the page here
   if (!Page.IsPostBack)
   {
      DataList1.DataSource = CreateDataSource();
      DataList1.DataBind();
   }
}
```

See Also

TemplateControl.LoadTemplate Method | Web Server Controls Templates | DataList Web Server Control | Customizing DataList Items at Run Time

Customizing DataList Items at Run Time

During page processing, the **DataList** control creates individual items that it will render to the page. To allow you to customize the items as they are being created, the **DataList** control raises two events:

- The **ItemDataBound** event is raised only for items, alternating items, and selected items. Use this event if the customization depends on the data.
- The **ItemCreated** event is raised for all items, including the header and footer. The event is raised for these items even if you have not created templates for them, in case you want to create them dynamically. For information on dynamically creating templates, see Creating Templates Dynamically in a DataList Web Server Control.

By responding to these events, you can change the items. A typical use is to change the appearance of the item based on the data being displayed in it. For example, if a numeric value you read from a database is negative, you might set the item's background color to red.

To customize items at run time using the ItemCreated event

1. Create an event handler for the **DataList** control's **ItemCreated** event. For details, see Creating Event Handlers in Web Forms Pages.
2. In the event handler, get the current item using the **Item** object from the *e* event-argument object. The index of the current item is available via the **Item** object's **ItemIndex** property, and its type is available via its **ItemType** property (which is defined using the **ListItemType** enumeration).

   > **Note** The **ItemIndex** property returns a positive value only for **Item**, **AlternatingItem**, and **SelectedItem** objects. The index value for header, footer, and separator items is -1.

   The following example shows how you can modify the background color of an item conditionally. The example uses the **ItemType** property and the **ListItemType** enumeration to set the background colors of the items. Items are set to **LightGoldenrodYellow**, alternating items are set to **DarkGoldenRod**, and the selected item is set to **Yellow**.

```
' Visual Basic
Private Sub DataList1_ItemCreated(ByVal sender As Object, _
ByVal e As System.Web.UI.WebControls.DataListItemEventArgs) _
Handles DataList1.ItemCreated
   Select Case e.Item.ItemType
      Case ListItemType.Item
         e.Item.BackColor = Color.LightGoldenrodYellow
      Case ListItemType.AlternatingItem
         e.Item.BackColor = Color.DarkGoldenrod
      Case ListItemType.SelectedItem
         e.Item.BackColor = Color.Yellow
      Case Else
         ' Add code here to hand the header, footer, and
         ' separator templates.
   End Select
End Sub

// C#
private void DataList1_ItemCreated(object sender,
System.Web.UI.WebControls.DataListItemEventArgs e)
{
   switch (e.Item.ItemType)
   {
      case System.Web.UI.WebControls.ListItemType.Item :
         e.Item.BackColor = Color.LightGoldenrodYellow;
         break;
      case System.Web.UI.WebControls.ListItemType.AlternatingItem :
         e.Item.BackColor = Color.DarkGoldenrod;
         break;
      case System.Web.UI.WebControls.ListItemType.SelectedItem :
```

```
            e.Item.BackColor = Color.Yellow;
            break;
        default :
            // Add code here to handle the header, footer, and
            // separator templates.
            break;
        }
    }
```

At the time that the **ItemCreated** event is raised, the individual controls in the templates have not yet been bound to data. However, the data is available in the **ItemDataBound** event.

To customize items at run time using the ItemDataBound event

1. Create an event handler for the **DataList** control's **ItemDataBound** event. For details, see Creating Event Handlers in Web Forms Pages.
2. In the event handler, use the **e.Item.DataItem** property to test the data that will be bound to the control and base a comparison on that.

   The following example shows how you can make a conditional test based on data. The example extracts the third field, Quantity field, from the **DataItem**. If the quantity is less than 10, the item in the **DataList** control is colored red.

```
' Visual Basic
Private Sub DataList1_ItemDataBound(ByVal sender As Object, _
ByVal e As System.Web.UI.WebControls.DataListItemEventArgs) _
Handles DataList1.ItemDataBound
   Dim drv As DataRowView = CType(e.Item.DataItem, DataRowView)
   Dim quantity As Integer = _
      Integer.Parse(drv.Row("Quantity").ToString())
   If (quantity < 10) Then
      e.Item.BackColor = Color.Red
   End If
End Sub

// C#
private void DataList1_ItemDataBound(object sender,
System.Web.UI.WebControls.DataListItemEventArgs e)
{
   DataRowView drv = (DataRowView)(e.Item.DataItem);
   int quantity = int.Parse(drv.Row["Quantity"].ToString());
   if (quantity < 10)
   {
      e.Item.BackColor = Color.Red;
   }
}
```

Responding to Button Events in DataList, Repeater, or DataGrid Items

If your **DataList**, **Repeater**, or **DataGrid** control templates include **Button**, **LinkButton**, or **ImageButton** Web Server controls, then these buttons can bubble their click events to the containing **DataList**, **Repeater**, or **DataGrid** control. This allows you to include buttons for functions not already defined for the **DataList** and **DataGrid** controls (edit, delete, update, and cancel) and to define functionality for the **Repeater** control.

To respond to button events in DataList, Repeater, and DataGrid controls

1. Include a **Button**, **LinkButton**, or **ImageButton** in a control template. Set the button's **CommandName** property to a string that identifies its function, such as "sort" or "copy".
2. Create a method for the **ItemCommand** event of the control. In the method, do the following:
   a. Check the **CommandName** property of the event-argument object's **CommandSource** property to see what string was passed.
   b. Perform the appropriate logic for the button that the user clicked.

   > **Note** If you call the **DataBind** method of the parent control (the **DataList**, **Repeater**, or **DataGrid** control), the **ItemCommand** event is not raised, because the contents of the parent control are reset. Therefore, you generally do not want to call the **DataBind** method on each round trip (that is, in the page initialization without checking for a post back). For details, see Data Binding Multi-Record Web Server Controls and Data Binding Single-Value Web Server Controls at Design Time.

   The following example shows how you can respond to a button click in a **DataList** control. In the example, the **ItemTemplate** contains an **ImageButton** control that displays a shopping cart. The button sends the command **AddToCart**. The **ItemCommand** event handler determines which button was clicked, and — if it was the shopping cart button — performs the appropriate logic.

```
' Visual Basic
Private Sub DataList1_ItemCommand(ByVal source As Object, _
ByVal e As System.Web.UI.WebControls.DataListCommandEventArgs) _
Handles DataList1.ItemCommand
   If (e.CommandName = "AddToCart") Then
      ' Add code here to add the item to the shopping cart.
      ' Use the value of e.Item.ItemIndex to find the data row
      ' in the data source.
    End If
End Sub

// C#
private void DataList1_ItemCommand(object source,
System.Web.UI.WebControls.DataListCommandEventArgs e)
{
   if (e.CommandName == "AddToCart")
   {
      // Add code here to add the item to the shopping cart.
      // Use the value of e.Item.ItemIndex to find the data row
      // in the data source.
   }
}
```

For an example using the **DataList** Web server control, see Allowing Users to Select Items in a DataList Web Server Control.

Specifying Flow or Table Format in a DataList Web Server Control

The **DataList** control allows you to display the items in the control in a variety of ways. You can specify that the control renders items in either flow mode (like a Word document) or in table mode (like an HTML table). Flow mode is suitable for simple layouts. Table mode gives you more precise control over layout and allows you to use table attributes (such as **CellPadding**).

To specify flow or table format at design time

- Set the **DataList** control's **RepeatLayout** property to **Flow** or **Table**.

To specify flow or table format programmatically

- Use the RepeatLayout enumeration, as shown in the following example:

```
' Visual Basic
DataList1.RepeatLayout = RepeatLayout.Flow

// C#
DataList1.RepeatLayout = RepeatLayout.Flow;
```

See Also

Introduction to the DataList Web Server Control | Specifying Horizontal or Vertical Layout in a DataList Web Server Control

Specifying Horizontal or Vertical Layout in a DataList Web Server Control

By default, the **DataList** Web server control displays a single column. However, you can specify any number of columns. Within the columns, you can specify how the items are ordered: vertically (the default) or horizontally. Vertical layout in three columns results in a layout such as the following:

```
1     4     7
2     5     8
3     6
```

Horizontal layout for the same items results in the following layout:

```
1     2     3
4     5     6
7     8
```

To specify column count and ordering at design time

1. Set the **DataList** control's **RepeatColumns** property to the number of columns you want.
2. Set the **RepeatDirection** property to **Vertical** or **Horizontal**.

To specify column count and ordering programmatically

- Specify the column count using the **RepeatColumns** property, and specify the ordering using the RepeatDirection enumeration, as shown in the following example:

```
' Visual Basic
DataList1.RepeatColumns = 2
DataList1.RepeatDirection = RepeatDirection.Horizontal

// C#
DataList1.RepeatColumns = 2;
DataList1.RepeatDirection = RepeatDirection.Horizontal;
```

DropDownList Web Server Control

The **DropDownList** Web server control enables users to select from a single-selection drop-down list box. The **DropDownList** control is very similar to the ListBox Web server control. It differs in that it shows only the selected item in a box, along with a drop-down button. When users click the button, a list of items is displayed.

The following table lists topics that provide information about how to work with the **DropDownList** control. Because the control is similar in many ways to the **ListBox** control, many of the links below lead you to topics for that control.

In This Section

Introduction to the DropDownList Web Server Control

The DropDownList Web server control allows users to select one or more items from a predefined list. It differs from the ListBox Web server control in that the list of items remains hidden until users click the drop-down button. In addition, the **DropDownList** control differs from the **ListBox** control in that it does not support multi-selection mode.

DropDownList Control Appearance

You can control the look of the **DropDownList** control by setting its height and width in pixels. Some browsers do not support setting the height and width in pixels and will use the row-count setting.

You cannot specify the number of items that are displayed in the list when users click the drop-down button. The length of the displayed list is determined by the browser.

As with other Web server controls, you can use style objects to specify the appearance of the control. For details, see Customizing the Appearance of ASP.NET Server Controls Using Styles.

Items

The **DropDownList** control is actually a container for the list items. Each item is a separate object with its own properties:

Property	Description
Text	The text displayed in the list.
Value	The value associated with an item. Setting this property allows you to associate a value with a specific item without displaying it. For example, you can set the **Text** property to the name of a U.S. state and the **Value** property to its postal abbreviation.
Selected	A Boolean value indicating whether the item is selected.

To work with items programmatically, you work with the Items collection of the **DropDownList** control. **Items** is a standard collection, and you can add item objects to it, delete items, clear the collection, and so on.

The currently selected item is available in the **DropDownList** control's SelectedItem property.

Binding Data to the Control

You can use a **DropDownList** Web server control to list options that are read from a data source. Each item in the **DropDownList** control corresponds to an item — typically a row — in the data source.

The control displays one field from the source. Optionally, you can bind the control to a second field to set the value (which does not display) of an item.

As with other server controls, you can bind any control properties, such as the color or size of the control, to data. For details, see Web Forms Data Binding.

DropDownList Events

The **DropDownList** control raises an event — SelectedIndexChanged — when users select an item. By default, this event does not cause the page to be posted to the server, but you can cause the control to force an immediate post by setting the AutoPostBack property to **true**.

> **Note** The ability of a **DropDownList** control to post to the server when it is checked requires that the browser support ECMAScript (JScript, JavaScript) and that scripting be enabled on the user's browser.

Adding DropDownList Controls to a Web Forms Page

The process of adding a **DropDownList** Web server control to a page consists primarily of setting options for how items should be displayed and whether users can select multiple items.

To add a DropDownList control to a Web Forms page

- In **Design** view, drag the **DropDownList** control from the Toolbox onto the page.

Adding items to the control is a separate process that depends on whether you will display a static list in the control or a list generated dynamically at run time. For details, see Adding Items in a List Web Server Control.

Gives directions for specifying Web server control properties in code.
Customizing the Appearance of ASP.NET Server Controls Using Styles
Gives directions for applying styles to change how controls are displayed.
Web Forms Data Binding
Provides basic conceptual information about binding data to Web Forms.

Introduction to the HyperLink Web Server Control

The HyperLink Web server control creates links on a Web page that allow users to move from page to page in your application. The primary advantage of using a **HyperLink** control is that you can set link properties in server code. For example, you can dynamically change the link text or target page based on conditions in your page.

> **Security Note** The URLs associated with a hyperlink can be tampered with by a malicious user. For more information, see Scripting Exploits.

Another advantage of using the **HyperLink** control is that you can use data binding to specify the target URL for the link (and parameters to be passed with the link, if necessary). A typical example is to create **HyperLink** controls based on a list of products; the target URL points to a page where the user can read more detail about the product.

> **Tip** If you need to create data-bound **HyperLink** controls, a convenient way to do so is to add them as children of a Repeater, DataList, or DataGrid control.

The **HyperLink** control can display clickable text or an image.

Unlike most Web server controls, the **HyperLink** control does not raise an event in server code when users click it. Instead, the control simply performs navigation.

See Also

Adding HyperLink Web Server Controls to a Web Forms Page | Adding Controls to a Web Forms Page Programmatically | Web Forms Data Binding

Adding HyperLink Web Server Controls to a Web Forms Page

HyperLink controls can render as text or as graphics.

To add a HyperLink control to a Web Forms page

1. Switch to **Design** view in the Web Forms Designer, and then drag a **HyperLink** control from the **Web Forms** tab of the Toolbox onto the page.
2. Specify the format of the link in the page by doing one of the following:
   - To create a text link, set the control's Text property. You can include HTML formatting in the property; for example, you can bold an individual word in the text by placing a <B> element around it in the **Text** property.
   - To create a graphical link, set the control's ImageUrl property to the URL of a .gif, .jpg, or other Web graphic file. For details about adding graphics to your project, see Adding and Removing Files in the File System Editor.

     Note If you set both the **ImageUrl** and **Text** properties, the **ImageUrl** property takes precedence.
3. Set the NavigateUrl property to the URL of the page to link to.

   Security Note The URLs associated with a hyperlink can be tampered with by a malicious user. For more information, see Scripting Exploits.
4. Optionally, set the ID of a target window or frame to display the linked page in. You can either specify a window by name or you can use predefined target values such as `_top`, `_parent`, and so on.

   Tip You can change the appearance of the link text — for example, whether it is underlined — using styles. For details, see Customizing the Appearance of ASP.NET Server Controls Using Styles.

   The following example shows how you can set the properties of a **Hyperlink** control at run time. The method handles a **Button** control's **Click** event and sets the control's link text and target page.

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As Object, ByVal e As System.EventArgs)
   Hyperlink1.Text = "Home"
   Hyperlink1.NavigateUrl = "http://www.microsoft.com/net/"
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   this.HyperLink1.Text = "Home";
   this.HyperLink1.NavigateUrl = "http://www.microsoft.com/net/";
}
```

Gives directions for applying styles to change how controls are displayed.
Web Forms Data Binding
Provides basic conceptual information about binding data to Web Forms.
Data Binding Single-Value Web Server Controls at Design Time
Gives directions for using data binding to specify the image for an **Image** control.

Introduction to the Image Web Server Control

The Image Web server control allows you to display images on a Web Forms page and manage the images in your own code.

You can specify the graphics file for an **Image** control at design time in the designer or at run time in a program. You can also bind the control's ImageURL property to a data source to display graphics based on database information. For details, see Data Binding Single-Value Web Server Controls at Design Time.

Unlike most other Web server controls, the **Image** control does not support any events; for example, it does not respond to mouse clicks. You can create an interactive image using the ImageButton Web server control.

Adding Image Web Server Controls to a Web Forms Page

The minimum action required to display an image is to create an **Image** control and point to a graphics file.

1. In **Design** view, drag an **Image** control from the **Web Forms** tab of the Toolbox onto the page.
2. Set the control's ImageURL property to the URL of a .gif, .jpg, or other Web graphic file. For details about adding graphics to your project, see Adding and Removing Files in the File System Editor.

   Security Note The URL associated with an **Image** control can be tampered with by a malicious user. For more information, see Scripting Exploits.

   Tip You can choose an image using the **Select Image** dialog box. To display it, click the ellipsis button (...) next to the **ImageUrl** property in the Properties window. For help with choosing an image, click **Help** in the dialog box.

   Note The control does not check that the URL you set is valid.

   For information about setting the **ImageUrl** property using data binding, see Data Binding Single-Value Web Server Controls at Design Time.

3. Optionally, set the following **Image** control properties.

Property	Description
Height and **Width**	Reserve space for the graphic on the page and resize the graphic to fit the reserved space. The image will be sized to fit the space you reserve.
ImageAlign	Aligns the image with respect to surrounding text, using values such as **Top**, **Bottom**, **Left**, **Middle**, and **Right**. In code, image alignment is set using the ImageAlign enumeration.
AlternateText	Displays text in place of the graphic if the graphic can't be loaded. In some browsers, this text is also displayed as a ToolTip.

Label Web Server Control

The **Label** Web server control provides a way to display text under programmatic control in a Web Forms page.

> **Note** If you want to display static text, you can present it using HTML; you do not need a **Label** control. Use a **Label** control only if you need to change the contents or other characteristics of the text in server code. If you are in linear layout mode, you can simply type text in. If you are in grid layout mode, you can add a **Linear Layout Panel** element and add static text inside of it.

The following topics provide information that you will find useful in learning to work with the **Label** Web server control.

In this Section

Introduction to the Label Web Server Control
Provides background information on the **Label** control.
Adding Label Web Server Controls to a Web Forms Page
Gives directions for placing a **Label** control on a page.

Web Forms Data Binding
Provides basic conceptual information about binding data to Web Forms.
Data Binding Single-Value Web Server Controls at Design Time
Gives directions for displaying data in a **Label** control.

Introduction to the Label Web Server Control

The Label Web server control provides you with a way to programmatically set text in a Web Forms page. You typically use the **Label** control when you want to change text in the page at run time, such as in response to a button click. A **Label** control is better for simply displaying text than a **TextBox** control (or another control) because the resulting text is static on the page; users cannot edit it.

> **Note** If you want to display static text, you can present it using HTML; you do not need a **Label** control. Use a **Label** control only if you need to change the contents or other characteristics of the text in server code. If you are in linear layout mode, you can simply type text in. If you are in grid layout mode, you can add a **Linear Layout Panel** element and add static text inside of it.

You can set the text of the **Label** control at design time in the designer or at run time in a program. You can also bind the Text property of a **Label** control to a data source to display database information on a page.

For details about data binding, see Data Binding Single-Value Web Server Controls at Design Time.

Using Labels in List Controls

The **Label** control is often used in list Web server controls (**Repeater**, **DataList**, and **DataGrid** controls) to display read-only information from a database. The usual strategy is to add a **Label** control to a template for one of these controls. You then bind the **Label** control to a data source (generally via the container list control). For details about templates, see Web Server Controls Templates.

Adding Label Web Server Controls to a Web Forms Page

You can add **Label** Web server controls as self-standing controls on the page. You can also make them child controls of other controls, such as using them in Web server control templates.

> **Note** If you want to display static text, you can present it using HTML; you do not need a **Label** control. Use a **Label** control only if you need to change the contents or other characteristics of the text in server code. If you are in linear layout mode, you can simply type text in. If you are in grid layout mode, you can add a **Linear Layout Panel** element and add static text inside of it.

To add a Label Web server control to a Web Forms page

1. In **Design** view, drag a **Label** control from the **Web Forms** tab of the Toolbox onto the page.
2. Set the control's Text property to the text to display. You can include HTML formatting in the property; for example, you can bold an individual word in the text by placing a `<B>` element around it in the **Text** property.

   The following example shows how you can set the text of a **Label** control at run time. The method handles a **Button** control's **Click** event and displays in the **Label** control whatever the user has typed into a **TextBox** control called **TextBox1**.

   > **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender as Object, ByVal e as EventArgs)
   Label1.Text = TextBox1.Text
End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e) {
   Label1.Text = TextBox1.Text;
}
```

Introduction to the ListBox Web Server Control

The ListBox Web server control allows users to select one or more items from a predefined list. It differs from a DropDownList control in that it can display multiple items at once and it optionally allows the user to select multiple items.

ListBox Control Appearance

The **ListBox** control is typically used to display more than one item at once. You can control the look of the list in these ways:

- Number of rows displayed You can set the control to display a specific number of items. If the control contains more items than that, it displays a vertical scrollbar.
- Height and width You can set the size of the control using pixels. In that case, the control ignores the number of rows you've set and displays as many as will fit into the height of the control. Some browsers do not support setting the height and width in pixels and will use the row count setting.

As with other Web server controls, you can use style objects to specify the appearance of the control. For details, see Customizing the Appearance of ASP.NET Server Controls Using Styles.

Items

The **ListBox** control is actually a container for the list items. Each list item is a separate object with its own properties:

Property	Description
Text	The text displayed in the list.
Value	The value associated with an item. Setting this property allows you to associate a value with a specific item without displaying it. For example, you can set the **Text** property to the name of an employee and the **Value** property to the employee's email alias.
Selected	A Boolean value indicating whether the item is selected. If the **ListBox** is set to allow multiple selections, more than one item can be selected.

To work with items programmatically, you usually access the Items of the **ListBox** control. **Items** is a standard collection, and you can add item objects to it, delete items, clear the collection, and so on. To test which items are selected, you can loop through the collection and test individual items.

For ease of use, the **ListBox** control also supports a property called SelectedItem. If the control is set to single-selection mode, this property returns the one selected item, making it unnecessary to loop through the entire **Items** collection to get at the current selection.

Single versus Multiple Selection

Users can normally select a single item in the list by clicking it. If you set the **ListBox** control to allow multiple selections, users can hold down the CTRL or SHIFT key while clicking to select multiple items.

Binding Data to the Control

You can use a **ListBox** Web server control to list options that are read from a data source. Each item in the **ListBox** control corresponds to an item — typically a row — in the data source.

The control displays one field from the source. Optionally, you can bind the control to a second field to set the value (which does not display) of an item.

As with other Web server controls, you can bind any control properties, such as the color or size of the control, to data. For details, see Web Forms Data Binding.

ListBox Events

The **ListBox** control raises an event — SelectedIndexChanged — when users select an item. By default, this event does not cause the page to be posted to the server, but you can cause the control to force an immediate post by setting the AutoPostBack property to **true**. If the **ListBox** control has been has been set to allow multiple selection and **AutoPostBack** is **true**, the form is posted back to the server with each selection. However, the current selection is maintained during each round trip.

Note The ability of a **ListBox** control to post to the server when it is checked requires that the browser support ECMAScript (JScript, JavaScript) and that scripting be enabled on the user's browser.

Adding ListBox Web Server Controls to a Web Forms Page

The process of adding a **ListBox** Web server control consists primarily of setting options for how items should be displayed and whether users can select multiple items.

To add a ListBox control to a Web Forms page

- In **Design** view, drag the **ListBox** control from the Toolbox onto the page, and then set the following properties:

Property	Description
Rows	Set to specify how many items should be displayed at once. **Note** You can also set the Height property to a pixel value. If you do, it takes precedence over t he value of the **Rows** property. However, not all browsers support the **Height** property, so you s hould set the **Rows** property also.
SelectionMode	Set to **Single** or **Multiple** to specify how many items users can select.

Adding items to the control is a separate process that depends on whether you will display a static list in the control or a list generated dynamically at run time. For details, see Adding Items in a List Web Server Control.

Adding Web Server Controls to a Web Forms Page | ListBox Class

Adding Items in a List Web Server Control

The information in this topic applies to all list Web server controls: ListBox, DropDownList, CheckBoxList, and RadioButtonList.

You can add items to a list Web server control in these ways:

- Add static items at design time.
- Add items programmatically at run time.
- Add items using data binding. For details, see Populating a List Web Server Control from a Database.

When you add a list item, you specify up to three possible properties of the item:

Property	Description
Text	The text displayed in the list.
Value	The value associated with an item. Setting this property allows you to associate a value with a specific item without displaying it. For example, you can set the **Text** property to the name of chemical element and the **Value** property to the symbol of the element.
Selected	A Boolean value indicating whether the item is selected. In a CheckBoxList control and in a multi-selection ListBox control, more than one item can be selected. In a DropDownList control, RadioButtonList control, and single-selection ListBox control, only one item can be selected at a time. If you set more than one selected item in these controls, the browser determines which item is rendered as selected.

To add static items at design time

1. In **Design** view, select the list control. In the Properties window, click the ellipsis button (...) for the Items property to open the **Collection Editor** dialog box.
2. Click **Add** to add a new item.
3. To set the properties for the new item, select it, and then in the **ListItem Properties** list, enter values for its **Text**, **Value**, and **Selected** properties.
4. Repeat Steps 2 and 3 for each item to add, and then choose **OK** to close the **Collection Editor** dialog box.

To add items programmatically

1. Create a new object of type **ListItem** and set its **Text** and **Value** properties.
2. Call the **Add** method of the control's **Items** collection and pass it the new object.

   The following example shows how to add **ListItem** objects to a **ListBox** control, but the procedure is identical for all list Web server controls.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button1.Click
   Me.ListBox1.Items.Add(New ListItem("Carbon", "C"))
   Me.ListBox1.Items.Add(New ListItem("Oxygen", "O"))
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   this.ListBox1.Items.Add(new ListItem("Carbon", "C"));
   this.ListBox1.Items.Add(new ListItem("Oxygen", "O"));
}
```

The following example shows how you can create new items programmatically. Using a loop, the code creates three new items in a **ListBox** control.

```
' Visual Basic
Private Sub Button2_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button2.Click
   Dim elements() As String = New String() {"Carbon", "Oxygen", "Hydrogen"}
   Dim i As Integer
   For i = 0 To ubound(elements)
      Me.ListBox1.Items.Add(New ListItem(elements(i)))
   Next
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   string[] elements = {"Carbon", "Oxygen", "Hydrogen"};
   int i;

   for (i = 0;i < elements.GetLength(0);i++)
   {
      this.ListBox1.Items.Add(new ListItem(elements[i]));
   }
}
```

Populating a List Web Server Control from a Database | Determining the Selection in a List Web Server Control | Setting the Selection in a List Web Server Control | ListBox Class

Determining the Selection in a List Web Server Control

The information in this topic applies to all list Web server controls: ListBox, DropDownList, CheckBoxList, and RadioButtonList.

One of the most common tasks in working with a list Web server control is to determine what item or items users have selected. The procedure varies depending on whether the list control allows single or multiple selections.

Use the following procedure when working with the **DropDownList** control, the **RadioButtonList** control, and a single-selection **ListBox** control.

> **Note** When you data bind a list control (by calling its **DataBind** method), the current list selection is lost. You generally do not want to call the **DataBind** method on each round trip (that is, in the page initialization without checking for a post-back), because doing so replaces the values in controls. For details, see Data Binding Multi-Record Web Server Controls.

To determine the selection in a single-selection list control

- Use one of the following methods:
  - To get the index value of the selected item, read the value of the SelectedIndex property. The index is zero-based. If nothing has been selected, the value of the property is -1.
  - To get the contents of the selected item, get the control's SelectedItem property. This property returns an object of type **ListItem**. You can get the contents of the selected item by getting the **Text** or **Value** property of the object.

    > **Security Note** Controls in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

  The following example shows how you can test which item is selected in a **RadioButtonList** control. The code first checks that there is a selection at all by reading the value of the **SelectedIndex** property, which is set to -1 until the user selects an item. It then gets the **SelectedItem** object and displays that object's **Text** property.

```
' Visual Basic
    Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs)
Handles Button1.Click

   ' Is anything selected? The index is -1 if nothing is selected.
   If RadioButtonList1.SelectedIndex > -1 Then
      Label1.Text="You chose: " & RadioButtonList1.SelectedItem.Text
   End If
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   // Is anything selected? The index is -1 if nothing is selected.
   if (RadioButtonList1.SelectedIndex > -1) {
      // The contents of the selection is available in the
      // SelectedItem objects, which provides the Text, Value,
      // and Selected properties.
      Label1.Text="You chose: " + RadioButtonList1.SelectedItem.Text;
   }
}
```

If the list control supports multiple selections, you must loop through the control and check for selected items one by one.

To determine the selection in a multi-selection list control

- Loop through the control's Items collection and test the **Selected** property of every individual item.

  The following example shows how you can test selections in a multi-selection **ListBox** control called ListBox1. The code displays a list of selected items in a label.

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Hand
les Button1.Click
   Dim msg As String
   Dim li As ListItem
   msg = ""
   For Each li In ListBox1.Items
      If li.Selected = True Then
         msg = msg & "<BR>" & li.Text & " selected."
   End If
   Next
   Label1.Text = msg
End Sub

// C#
public void Button1_Click(object sender, System.EventArgs e)
{
   // Text that will display selected items
   string msg = "" ;
   foreach(ListItem li in ListBox1.Items)
   {
      if(li.Selected == true)
         {
            msg += "<BR>" + li.Text + " is selected.";
         }
   }
   Label1.Text = msg;
}
```

Setting the Selection in a List Web Server Control | ListBox Class

Populating a List Web Server Control from a Database

The information in this topic applies to all list Web server controls: ListBox, DropDownList, CheckBoxList, and RadioButtonList.

You can use a list Web server control to display items that are read from a data source. Each item in the control corresponds to an item — typically a row — in the data source. The control can display one field from the source and can optionally use a second field as the item value.

To populate a list control from a database

1. Set the control's DataSource property to a reference to a data source for the page.
2. Specify which fields in the data source should be used to populate each item by setting the following control properties:

   - DataTextField The name of the field whose value will be displayed in the list.
   - DataTextFormatString A formatting expression for the list item text. For information about creating a formatting expression, see Composite Formatting.
   - DataValueField The name of the field to be used for the **Value** property of each list item.

   If the data source has only one field, you do not have to explicitly set these fields, because the control will simply display the single field.

Responding to Changes in a List Web Server Control

The information in this topic applies to all list Web server controls: ListBox, DropDownList, CheckBoxList, and RadioButtonList.

When the user makes a selection in list Web server control, the control raises an event that you can respond to directly. Normally you do not need to respond directly to the selection event at all. Instead, it is more typical to test which item is selected after the form has been posted to the server by a control such as a Button control. For details about determining which item is selected, see Determining the Selection in a List Web Server Control.

To respond directly to changes in a list Web server control

- Create an event handler for the control's SelectedIndexChanged event.

  By default, the **SelectedIndexChanged** event does not immediately cause the Web Forms page to be posted to the server. Instead, the event is raised in server code the next time the form is posted (as when a **Button** Web server control is clicked). To have the **SelectedIndexChanged** event cause an immediate posting, set the control's AutoPostBack property to **true**.

  > **Note** The event is raised as soon as the user makes a selection in the list control. If the **AutoPostBack** property is **true**, the form is posted with each selection, but the selected items are preserved with each round trip.

  The following example shows how you can respond to a selection in a **DropDownList** control. The event handler displays the user's selection in a **Label** control.

  > **Security Note** Controls in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

```
' Visual Basic
Private Sub DropDownList1_SelectedIndexChanged(ByVal sender As System.Object, ByVal e As
System.EventArgs) Handles DropDownList1.SelectedIndexChanged
   Label1.Text = "You selected " & DropDownList1.SelectedItem.Text
End Sub

// C#
private void DropDownList1_SelectedIndexChanged(object sender, System.EventArgs e)
{
   Label1.Text = "You selected " + DropDownList1.SelectedItem.Text;
}
```

ASP.NET Server Control Event Model | Creating Event Handlers in Web Forms Pages | ListBox Class

Setting the Selection in a List Web Server Control

The information in this topic applies to all list Web server controls: ListBox, DropDownList, CheckBoxList, and RadioButtonList.

Normally, users select items in a list Web server control to indicate their choice. However, you might want to preselect items or select items at run time (programmatically) based on some condition.

To set the selection in a list Web server control at design time

1. In **Design** view, select the control. In the Properties window, click the ellipsis button (...) for the Items property to open the **Collection Editor** dialog box.
2. From the **Members** list, choose the member to be selected, and then set its **Selected** property to true.
3. If the control is set to allow multiple selection, repeat Step 2 for each item to select, and then choose **OK** to close the **Collection Editor** dialog box.

To set a single selection in a list Web server control programmatically

- Set the control's SelectedIndex property to the index value of the item to select. The index is zero-based. To set no selection, set **SelectedIndex** to -1.

```
' Visual Basic
ListBox1.SelectedIndex = 2
' Selects the third item

// C#
ListBox1.SelectedIndex = 2;
// Selects the third item
```

To set multiple selections in a list control programmatically

- Loop through the control's **Items** collection and set the **Selected** property of every individual item.

  Note You can only select multiple items if the control's SelectionMode property is set to **Multiple**.

  The following example shows how you can set selections in a multi-selection **ListBox** control called ListBox1. The code selects every other item.

```
' Visual Basic
Protected Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) H
andles Button1.Click
   Dim i As Integer
   Dim li As ListItem
   For Each li In ListBox1.Items
      i += 1
      If (i Mod 2 = 0) Then
         li.Selected = True
      End If
   Next
End Sub

// C#
public void Button1_Click(object sender, System.EventArgs e)
{
   // Counter
   int i = 0;
   foreach(ListItem li in ListBox1.Items)
   {
      if( (i%2) == 0)
      {
         li.Selected = true;
```

```
        }
        i += 1;
    }
}
```

Literal Web Server Control

The **Literal** control renders static text into a Web page without adding any HTML elements. You can manipulate the text programmatically with server code.

> **Note** If you want to display static text, you can present it using HTML; you do not need a **Literal** control. Use a **Literal** control only if you need to change the contents in server code.

The following topics provide information that you will find useful in learning to work with the **Literal** Web server control.

In This Section

Introduction to the Literal Web Server Control
Provides background information on the **Literal** control.
Adding Literal Web Server Controls to a Web Forms Page
Gives directions for placing a **Literal** control on a page.

Related Sections

Setting Web Server Control Properties Programmatically
Gives directions for specifying Web server control properties in code.
Customizing the Appearance of ASP.NET Server Controls Using Styles
Gives directions for applying styles to change how controls are displayed.
Web Forms Data Binding
Provides basic conceptual information about binding data to Web Forms.

Introduction to the Literal Web Server Control

You can use a Literal Web server control to render static text into a Web page and manipulate that text using server code. Unlike the **Label** Web server control, the **Literal** control does not add any HTML elements to the text.

As an example, you might want to create a simple vertical list of text elements that can be programmatically manipulated. You can do this by setting the **Text** property either of a **Label** control or of a **Literal** control to the HTML content that you want to send to the Web page. If you use a **Label** control, the control is wrapped in an HTML tag. The does not affect the rendering of the page in any noticeable way. If you use a **Literal** control, the tag is not added, which allows your code to be simpler.

You cannot apply styles to the content of the **Literal** control. This means that the **Literal** control cannot be positioned when the Web Forms Designer is in grid mode; as a consequence, the **Literal** control might not be suitable for creating captions. In addition, you cannot address the control with client code.

See Also

Adding Literal Web Server Controls to a Web Forms Page | Literal Web Server Control | Literal Class

Adding Literal Web Server Controls to a Web Forms Page

Add a **Literal** Web server control to your page when you want to set text programmatically without adding extra HTML tags.

> **Note** If you want to display static text, you can present it using HTML; you do not need a **Literal** control. Use a **Literal** control only if you need to change the contents in server code.

To add a Literal control to a Web Forms page

1. In Design view, drag a **Literal** control from the **Web Forms** tab of the Toolbox onto the page.

   The following example shows a simple page that displays a headline at run time. The body of the page, including the **Literal** control, might look like this:

   ```
   <body>
      <form runat="server">
         <H1><asp:Literal id="Headline" runat=server /></H1>
      </form>
   </body>
   ```

2. Add code to your page to set the control's Text property at run time.

   The following example shows how to programmatically set the text of the **Literal** control.

   ```
   ' Visual Basic
   Sub Page_Load(ByVal sender As System.Object, _
         ByVal e As System.EventArgs) Handles MyBase.Load
      Headline.Text = "New Web Site Announced"
   End Sub

   // C#
   private void Page_Load(object sender, System.EventArgs e)
   {
      Headline.Text = "New Web Site Announced";
   }
   ```

Gives directions for adding child controls to a **Panel** control at run time.
CheckBox and CheckBoxList Web Server Controls
Gives information on creating grouped check boxes.
RadioButton and RadioButtonList Web Server Controls
Gives information on creating grouped radio buttons.

Introduction to the Panel Web Server Control

The Panel Web server control provides a container control within a Web Forms page that you can use as a parent for static text and for other controls. The **Panel** control is suitable for:

- **Group Behavior** You can manage a group of controls as a unit by putting them in a panel and then manipulating the panel. For example, you can hide or show a group of controls inside a panel by setting the panel's **Visible** property.
- **Dynamic Control Generation** The **Panel** control provides a convenient container for controls that you create at run time.
- **Appearance** The **Panel** control supports appearance properties such as **BackColor** and **BorderWidth** that you can set to create a unique look for local area on a page.

> **Note** The **Panel** control is not required to group controls such as **RadioButton** controls.

Adding Panel Controls to a Web Forms Page

To use a **Panel** Web server control, you add it to a page and then add controls and static text to it.

To add a Panel control to a Web Forms page

1. Switch to Design view in the Web Forms Designer, and then drag a **Panel** control from the **Web Forms** tab of the Toolbox onto the page.

   The control is initially displayed with the static text "Panel" in it. To work with static text in the control, see below.

2. Optionally, drag the panel's borders to resize the control.

   > **Note** The control automatically resizes itself to display all its child controls, even if they exceed the height you have set.

3. Optionally, set the following properties of the **Panel** control to specify how the pane interacts with its child controls.

Property	Description
HorizontalAlign	Specifies how the child controls are aligned within the panel (left, right, centered, or justified).
Wrap	Specifies whether content that is too wide for the panel is wrapped to the next line or truncated at the panel's edge.

You can add and remove text directly in **Design** view.

To work with static text in the Panel control at design time

1. Place the pointer where you want to edit in the **Panel** control, and then click the control once to select it. When you see selection handles on the border, click again to put the control into text-editing mode. (If you click too quickly the second time, the designer will treat your click as a double click and switch to the Code Editor).

   When the panel is in text-editing mode, it displays a shaded border and the mouse pointer becomes an insertion point.

2. Edit text within the **Panel** control as you do on the page.

   > **Note** To add static text to the **Panel** control at run time, you create a LiteralControl object and set its **Text** property. You then programmatically add the **LiteralControl** object to the panel the way you would any control. For details on adding controls, see Adding Controls to a Web Forms Page Programmatically.

After adding a **Panel** control to a page, you can add controls. You can do this at design time or at run time.

To add controls to a Panel control at design time

- To add controls, drag them from the Toolbox into the **Panel** control. If necessary, the panel will resize itself to accommodate the control.

  > **Tip** If you want to be able to position controls in the panel using x and y coordinates, first drag a Grid Layout Panel control from the HTML tab of the Toolbox into the panel and size it to fit. You can then drag controls onto the panel and position them with the mouse.

For details about adding controls at run time, see Adding Controls to a Web Forms Page Programmatically.

Web Forms Data Binding
Provides basic conceptual information about binding data to Web Forms.

Introduction to the PlaceHolder Web Server Control

The PlaceHolder Web server control enables you to place an empty container control within the page and then dynamically add, remove, or loop through child elements at run time. The control only renders its child elements; it has no HTML-based output of its own.

As an example, you might want to have a variable number of buttons appear on a Web page, depending on options selected by users. That way, users are not confronted with potentially confusing choices that are either unavailable or not relevant to their individual needs.

Adding PlaceHolder Web Server Controls to a Web Forms Page | PlaceHolder Class | PlaceHolder Web Server Control

Adding PlaceHolder Web Server Controls to a Web Forms Page

Add a **PlaceHolder** Web server control to your page when you want to dynamically add, remove, or loop through controls at run time.

To add a PlaceHolder control to a Web Forms page

- In Design view, drag a **PlaceHolder** control from the **Web Forms** tab of the Toolbox onto the page.

To add child controls to a PlaceHolder control at run time

1. Create an instance of the control you want to add to the **PlaceHolder** control.
2. Call the Add method of the **PlaceHolder** control's Controls property, passing it the instance you created.

   The following example shows how to add three **HtmlButton** controls as children of a **PlaceHolder** control.

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
      ByVal e As System.EventArgs) Handles MyBase.Load
   Dim btnClick As HtmlButton = New HtmlButton()
   btnClick.InnerText = "Button 1"
   PlaceHolder1.Controls.Add(btnClick)
   btnClick = New HtmlButton()
   btnClick.InnerText = "Button 2"
   PlaceHolder1.Controls.Add(btnClick)
   btnClick = New HtmlButton()
   btnClick.InnerText = "Button 3"
   PlaceHolder1.Controls.Add(btnClick)
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   HtmlButton btnClick = new HtmlButton();
   btnClick.InnerText = "Button 1";
   PlaceHolder1.Controls.Add(btnClick);
   btnClick = new HtmlButton();
   btnClick.InnerText = "Button 2";
   PlaceHolder1.Controls.Add(btnClick);
   btnClick = new HtmlButton();
   btnClick.InnerText = "Button 3";
   PlaceHolder1.Controls.Add(btnClick);
}
```

RadioButton and RadioButtonList Web Server Controls

The **RadioButton** and **RadioButtonList** Web server controls allow users to select one item from a short, predefined list. The following topics provide information that you will find useful in learning to work with these two controls.

Because there are two different controls, and because they function somewhat differently, it's important to understand their different purposes. You can refer to the following table to determine which topics pertain specifically to the control you want to work with.

> **Note** Some of the topics listed below for the **RadioButtonList** control do not pertain solely to that control; instead, they are topics that apply to all list Web Server controls (ListBox, DropDownList, CheckBoxList, and **RadioButtonList**).

Introduction to the RadioButton and RadioButtonList Web Server Controls

You can use two types of Web server controls to add radio buttons to a Web Forms page: individual RadioButton controls or a RadioButtonList control. Both controls allow users to select from a small set of mutually exclusive, pre-defined choices. The controls allow you to define any number of radio buttons with labels and to arrange them horizontally or vertically.

> **Note** You can also use the HtmlInputRadioButton server control to add radio buttons to a Web Forms page. For details about the differences between Web and HTML controls, see Introduction to ASP.NET Server Controls.

> **Tip** If you want to present users with a longer list of options or a list that might vary in length at run time, use a ListBox or DropDownList Web server control.

RadioButton Control versus RadioButtonList Control

You add individual **RadioButton** controls to a page and work with them singly. Typically, you group two or more individual buttons together. See Adding Individual RadioButton Controls to a Web Forms Page.

In contrast, the **RadioButtonList** control is a single control that acts as a parent control for a collection of radio button list items. It derives from a base ListControl Class, and therefore works much like the **ListBox**, **DropDownList**, and CheckBoxList Web server controls. Therefore, many of the procedures for working with the **RadioButtonList** control are the same as they are for the other list Web server controls.

Each type of control has advantages. Individual **RadioButton** controls give you more control over the layout of the radio button group. For example, you can include text (that is, non-radio-button text) between each radio button.

The **RadioButtonList** control does not permit you to insert text between the buttons, but is far easier to use if you want to bind the buttons to a data source. It is also slightly easier to write code that checks which button has been selected.

Grouping Radio Buttons

Radio buttons are rarely used singly. Instead, they are grouped to provide a set of mutually exclusive options. Within a group, only one radio button can be selected at a time. You can create grouped radio buttons in these ways:

- Add individual RadioButton Web server controls to a page and then manually assign them all to a group. In this case, the group is an arbitrary name; all radio buttons with the same group name are considered part of a single group.
- Add a RadioButtonList Web server control to the page. The list items in the control are automatically grouped.

RadioButton Events

Events work slightly differently between individual **RadioButton** controls and the **RadioButtonList** control.

Individual RadioButton Controls

Individual **RadioButton** controls raise an event — CheckedChanged — when users click the control. By default, this event does not cause the page to be posted to the server, but you can have the control force an immediate post by setting the AutoPostBack property to **true**. For details about responding to this event directly, see Responding to a User Selection in a RadioButton Group.

> **Note** The ability of a **RadioButton** control to post to the server when it is checked requires that the browser support ECMAScript (Jscript, JavaScript) and that scripting be enabled on the user's browser.

Whether a **RadioButton** control posts to the server or not, it is not usually necessary to create an event handler for the **CheckedChanged** event. Instead, it is more common to test which button is selected when the form has been posted to the server by a control such as a **Button** control. For details, see
Setting and Getting the Selection in a RadioButton Web Server Control.

RadioButtonList Control

In contrast, the **RadioButtonList** control raises a SelectedIndexChanged event when users change which radio button in the list is selected. By default, the event does not cause the form to be posted to the server, although you can specify this option by setting the AutoPostBack property to **true**. For details, see Responding to Changes in a List Web Server Control.

> **Note** The ability of a **RadioButtonList** control to post to the server when it is checked requires that the browser support ECMAScript (JScript, JavaScript) and that scripting be enabled on the user's browser.

As with individual **RadioButton** controls, it is more common to test the state of the **RadioButtonList** control after the form has been posted some other way. For details, see Determining the Selection in a List Web Server Control.

Binding Data to the Control

As with any Web server control, you can bind an individual **RadioButton** control to a data source, and you can bind any property of the **RadioButton** control to any field of the data source. For example, you might set the control's Text property from information in a database.

However, because radio buttons are used in groups, binding a single radio button to a data source isn't a common scenario. Instead, it's more typical to bind a **RadioButtonList** control to a data source. In that case, the data source dynamically generates radio buttons (list items) for each record in the data source.

For general information about data binding Web server controls, see
Data Binding Single-Value Web Server Controls at Design Time.

Adding Individual RadioButton Controls to a Web Forms Page

You can add radio buttons to a Web Forms page in two ways:

- By adding individual **RadioButton** Web server controls and grouping them.
- By adding a **RadioButtonList** control and adding individual list items to the control.

For details about the differences in these approaches, see
Introduction to the RadioButton and RadioButtonList Web Server Controls.

> **Note** This topic addresses how to add individual **RadioButton** controls to the page. For details about adding a **RadioButtonList** control, see Adding RadioButtonList Controls to a Web Forms Page.

When you use individual the **RadioButton** Web server controls, you typically add a set of them to the page and then group them. You can create multiple separate groups of buttons.

To add individual RadioButton controls to a Web Forms page

1. In Design view, drag a **RadioButton** control from the **Web Forms** tab of the Toolbox onto the page.
2. Specify a caption by setting the Text property.
3. Optionally, change the orientation of the caption by setting the TextAlign property.
4. Repeat Steps 1 through 3 for each radio button.

To group individual RadioButton controls

- Set the GroupName property of each control to the same name. You can use any string as the name, but do not include a space. For example, you might assign the string "RadioButtonGroup1" to the **GroupName** property of all the buttons.

  To create multiple groups, use a different group name for each.

  > **Note** You can add **RadioButton** controls to the page and group them with existing groups at any point.

See Also

Setting and Getting the Selection in a RadioButton Web Server Control | Responding to a User Selection in a RadioButton Group | RadioButton Class | RadioButtonList Class

Adding RadioButtonList Controls to a Web Forms Page

When you use a **RadioButtonList** control, you add a single control to the page. Adding items to the control is a separate process that depends on whether you will display a static list in the control or a list generated dynamically at run time. For details, see Adding Items in a List Web Server Control.

> **Note** The procedure for working with individual **RadioButton** Web server controls is different. For details, see Adding Individual RadioButton Controls to a Web Forms Page.

To add a RadioButtonList control to a Web Forms page

1. In Design view, drag a **RadioButtonList** control from the **Web Forms** tab of the Toolbox onto the page.
2. Optionally, change the orientation of the caption by setting the TextAlign property.
3. Optionally, change the layout of the control to display multiple columns. For details, see Setting Layout in a RadioButtonList Web Server Control.

See Also

Introduction to the RadioButton and RadioButtonList Web Server Controls | Adding Individual RadioButton Controls to a Web Forms Page | Setting Layout in a RadioButtonList Web Server Control | Adding Items in a List Web Server Control | Setting the Selection in a List Web Server Control | Determining the Selection in a List Web Server Control | RadioButton Class | RadioButtonList Class

Responding to a User Selection in a RadioButton Group

When the user selects a **RadioButton** control, the control raises an event that you can respond to.

> **Note** The **RadioButtonList** control raises events differently than individual **RadioButton** controls. For details, see Responding to Changes in a List Web Server Control.

You might not need to respond directly to the selection event of a **RadioButton** control at all. You respond to the event only if it's important to know when the user has made a change to the selection in a radio button group.

If you are only interested in knowing which radio button is selected, and not whether selection has changed, you can simply test radio button selection after the form has been posted to the server by a control such as a Button control. For details about determining which **RadioButton** control is selected, see Setting and Getting the Selection in a RadioButton Web Server Control.

Because each **RadioButton** Web server control is a separate control, each can raise an event individually; the radio button group does not raise an event as a whole.

To respond to a selection in a RadioButton control

- Create an event handler for the control's CheckedChanged event.

  By default, the **CheckedChanged** event does not immediately cause the Web Forms page to be posted to the server. Instead, the event is raised in server code the next time the form is posted, as when a **Button** Web server control is clicked. To have the **CheckedChanged** event cause an immediate posting, set the **RadioButton** control's AutoPostBack property to **true**.

  > **Note** The ability of a **RadioButton** control to post to the server when it is checked requires that the browser support ECMAScript (JScript, JavaScript) and that scripting be enabled on the user's browser.

  The following example shows how you can respond when a user selects a **RadioButton** control.

```
' Visual Basic
Sub RadioButton1_CheckedChanged(sender As Object, e As EventArgs) Handles RadioButton1.Ch
eckedChanged
   Label1.Text = "You selected Radio Button " & RadioButton1.Text
End Sub

// C#
public void RadioButton1_CheckedChanged (object sender, System.EventArgs e)
{
   Label1.Text = "You selected Radio Button " + RadioButton1.Text;
}
```

Adding Individual RadioButton Controls to a Web Forms Page |
Setting and Getting the Selection in a RadioButton Web Server Control | Responding to a User Selection in a RadioButton Group |
RadioButton Class | RadioButtonList Class

Setting and Getting the Selection in a RadioButton Web Server Control

You can set a selected radio button at design time or at run time in code. If the radio button is in a group, setting it clears any other selection in the group.

> **Note** If you are working with a **RadioButtonList** control, the procedure for getting and setting the value of a button is different. For details, see Determining the Selection in a List Web Server Control and Setting the Selection in a List Web Server Control.

To set the selected RadioButton control

- Set the control's Checked property to **true**. If you select more than one **RadioButton** control in a group, the browser determines which button is rendered as selected.

  If you set the property to **false**, it clears the selection but does not select another radio button. Therefore, you can clear all selections by setting the **Checked** property of all radio buttons in a group to **false**.

Determining which **RadioButton** control has been selected is a matter of testing the **Checked** property.

To determine which RadioButton control in a group is selected

- Test the control's **Checked** property.

  > **Note** Testing the value of a radio button does not tell you if the user changed the value of the control, only if it is selected. To check for a change in the control, write an event handler for the control's CheckedChanged event. For details, see Responding to a User Selection in a RadioButton Group.

  To determine which is checked in a group, you have to test each control individually, as in the following example:

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles But
ton1.Click
   Dim msg As String = "You selected "
   If RadioButton1.Checked = True Then
      msg = msg & RadioButton1.Text
   ElseIf Radiobutton2.Checked = True Then
      msg = msg & RadioButton2.Text
   ElseIf Radiobutton3.Checked = True Then
      msg = msg & RadioButton3.Text
   End If
   Label1.text = msg
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   if (RadioButton1.Checked) {
      Label1.Text = "You selected " + RadioButton1.Text;
   }
   else if (RadioButton2.Checked) {
      Label1.Text = "You selected " + RadioButton2.Text;
   }
   else if (RadioButton3.Checked) {
      Label1.Text = "You selected " + RadioButton3.Text;
   }
}
```

Setting Layout in a RadioButtonList Web Server Control

By default, the **RadioButtonList** Web server control displays a single column of buttons. However, you can specify any number of columns, and within the columns, you can specify how the items are ordered: vertically (the default) or horizontally. Vertical layout in three columns results in a layout such as the following:

```
A     D     G
B     E     H
C     F
```

Horizontal layout for the same items results in the following layout:

```
A     B     C
D     E     F
G     H
```

> **Note** If you are working with individual **RadioButton** Web server controls, you don't set layout as a property of the control. Instead, you set it by simply adding the radio buttons within the page flow. For details about the differences between these controls, see Introduction to the RadioButton and RadioButtonList Web Server Controls.

To specify column count and ordering:

1. In the Properties window, set the **RadioButtonList** control's RepeatColumns property to the number of columns you want.
2. Set the RepeatDirection property to **Vertical** or **Horizontal**. If you are setting the property in code, use the **RepeatDirection** enumeration, as shown in the following example:

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles But
ton1.Click
   ' Create five radio buttons, labeled Red, Blue, Green, Yellow, and Orange.
   Dim colors() As String = _
      New String() {"Red", "Blue", "Green", "Yellow", "Orange"}
   RadioButtonList1.Items.Clear()
   Dim i As Integer
   For i = 0 To ubound(colors)
      RadioButtonList1.Items.Add(colors(i))
   Next
   ' Layout the radio buttons horizontally.
   RadioButtonList1.RepeatDirection = RepeatDirection.Horizontal
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e)
{
   // Create five radio buttons, labeled Red, Blue, Green, Yellow, and Orange.
   string[] colors = {"Red", "Blue", "Green", "Yellow", "Orange"};
   this.RadioButtonList1.Items.Clear();
   for(int i=0;i < colors.GetLength(0);i++){
      this.RadioButtonList1.Items.Add(colors[i]);
   }
   // Layout the radio buttons horizontally.
   this.RadioButtonList1.RepeatDirection = RepeatDirection.Horizontal;
}
```

Repeater Web Server Control

The Repeater Web server control is a data-bound container control that produces a list of individual items. You define the layout of individual items on a Web page using templates. For an overview, see Web Server Controls Templates. When the page is run, the control repeats the layout for each item in the data source.

> **Note** For information on the differences between the **Repeater**, **DataList**, and **DataGrid** Web server controls, see Controls for Displaying Lists On Web Pages.

The following topics provide information that you will find useful in learning to work with the **Repeater** control.

Introduction to the Repeater Web Server Control

The **Repeater** Web server control is a basic container control that allows you to create custom lists out of any data available to the page. The control does not have an inherent look — for example, it does not by default create a vertical list of data or a table. Instead, you provide the layout for the control by creating templates. When the page runs, the **Repeater** control loops through the records in the data source and renders an "item" (or alternating item) for each record.

Because the **Repeater** control has no default look, it is useful for creating virtually any kind of list. Examples of how you can use the **Repeater** control to display information include:

- In a table layout
- In a comma-delimited list (for example, "a, b, c, d, ...")
- In a bulleted list or numbered list

Templates

To use the **Repeater** control, you create templates that define the layout of the control's content. Templates can contain any combination of HTML text and controls that are valid on a Web Forms page. If no templates are defined, or if none of the templates contain elements, the control does not appear on the page when the application is run.

The **Repeater** control supports the following templates:

Template	Description
ItemTemplate	Elements that are rendered once for each row in the data source. To display data in the **ItemTemplate**, you add one or more Web server or HTML server controls to the template and bind the controls to a data source.
AlternatingItemTemplate	Like the **ItemTemplate** element, but rendered for every other row in the **Repeater** control. You can specify a different look for the **AlternatingItemTemplate** element by setting its style properties.
HeaderTemplate and **FooterTemplate**	Elements to render once before and after all data-bound rows have been rendered. For example, you can have an HTML Table span the entire repeater by putting the opening tag, <TABLE>, in the **HeaderTemplate** and putting the closing tag, </TABLE> in the **FooterTemplate**.
SeparatorTemplate	Elements to render between each row, such as line breaks (tags), lines (<HR> tags), or commas.

For more information, see Web Server Controls Templates and Creating Web Server Control Templates.

Working with the Repeater Control at Design Time

The Web Forms Designer provides only limited what-you-see-is-what-you-get (WYSIWYG) editing for the **Repeater** control. You can drag the control onto a page and set its base properties as you do with any other control on the page.

However, to specify templates for the **Repeater** control, you work in the HTML view of the Web Forms Designer. The control allows you to specify incomplete HTML elements for templates — for example, a <TABLE> tag in the **HeaderItem** template and a </TABLE> element in the **FooterItem** template. Because the Design view of the Web Forms Designer always checks the validity of the HTML markup in a page, it will not accept element fragments of this sort. As a consequence, template editing for the **Repeater** control is done in HTML view.

> **Note** Warnings will be displayed in the task list when HTML tags are split across templates. You can safely ignore these warnings. The HTML elements will be displayed correctly when the application is run.

Binding Data to the Control

The **Repeater** control must be bound to a data source via its **DataSource** property or it will not render. The control can use as a data source any class that supports the IEnumerable interface. In practical terms, this means that you can use any type of data source that you can create using the Visual Studio data designers. You can also use data sources that you add to your page from the Toolbox, such as the **DataSet** or **DataView** class. You can also bind to simpler structures, such as an array.

Controls in the templates may be bound to the data source of the **Repeater** control or to a separate data source. Binding the controls to the **Repeater** control guarantees that all the controls will display data items from the same data row. The syntax for binding the controls to the **Repeater** control uses "Container" as the data source, since the **Repeater** is the container for all the controls. The binding command has the following form:

```
<%# DataBinder.Eval(Container, "DataItem.PhoneNumber") %>
```

Alternatively, a control may be bound to a data source that is not the same as the **Repeater** control's data source. This method might be used if you want the control to display a different row of data from the **Repeater** control's data source or if you want the control to have a completely different data source. For example, the **Repeater** item template might display the name and occupation of an employee from one table, while a **ListBox** control contains a selection of occupations from a different table.

> **Note** You cannot bind controls in the header, footer, and separator templates using **DataBinder.Eval** expressions in HTML view. You must bind these controls in the code.

When the page runs, you call the **Repeater** control's **DataBind** method to get the records to be displayed. You call the method again (for example, in an event handler) each time you need to refresh the data being displayed.

For an overview of data binding in Web server controls, see Data Access in Web Forms Pages and Adding Repeater Controls to a Web Forms Page.

Events

The **Repeater** control supports several events. The Repeater.ItemCreated event is called each time the table is rendered and allows you to customize the item-creation process. For example, if you were using a repeater control to display a to-do list, you could display overdue items in red text, completed items in black text, and other tasks in green text.

The Repeater.ItemCommand Event is raised in response to button clicks in individual items. The event is designed to allow you to embed a **Button**, **LinkButton**, or **ImageButton** Web server control in an item template and then be notified if a user clicks the button. When a click occurs, the event is bubbled up to the **Repeater** control. The most common uses for the **ItemCommand** event are to program add, update, and delete behaviors to the **Repeater** control. Since all the button clicks raise the same **ItemCommand** event, there must be way to distinguish which button has been clicked. You can determine which button was clicked by setting each button's **CommandName** property to a unique string value. The **ItemCommand** property of the **RepeaterCommandEventArgs** parameter contains the **CommandName** of the button clicked.

For more information, see Responding to Button Events in DataList, Repeater, or DataGrid Items.

Adding Repeater Controls to a Web Forms Page

Adding a **Repeater** Web server control to a page requires several steps. The following procedure describes the minimum that you must do to create a working **Repeater** control.

To add a Repeater Web server control to a Web Forms page

1. Add a data source to the Web Forms page. There are several methods for handling data on a page. To choose an appropriate method, see Introduction to Data Access with ADO.NET and Introduction to Data Access in Web Forms Pages.
2. In Design view, drag a **Repeater** control from the **Web Forms** tab of the Toolbox onto the page.
3. Set the control's **DataSource** property. In the Properties window, the drop-down list for the **DataSource** property will display all the data sources, such as **DataSet** and **DataView** controls, defined on the page.
4. Call the control's **DataBind** method. This is typically done in the page's **Page_Load** event using code such as the following, where the Repeater1 control is bound to a **DataSet** object. Since the **DataSet** was bound to the **Repeater** control in the designer, it does not need to be done in the code:

```
' Visual Basic
Protected Sub Page_Load(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles MyBase.Load
   ' Put user code to initialize the page, including data, here.
   Repeater1.DataBind()
End Sub

// C#
protected void Page_Load(object sender, EventArgs e)
{
   // Put user code to initialize the page, including data, here.
   Repeater1.DataBind();
}
```

5. Switch to HTML view.
6. Create templates inside the **Repeater** element that contain HTML text and controls to display the data. For details see Web Server Controls Templates. The skeleton for an **ItemTemplate** element might look like this:

```
<asp:repeater id=Repeater1 runat="server" datasource="<%# dataView1 >">
   <ItemTemplate>
   </ItemTemplate>
</asp:repeater>
```

7. Add any combination of HTML elements and Web server controls to the templates to display the data source information.

   You must bind the controls to the data by including a data-binding expression. Typically, you bind them to the container control. An **ItemTemplate** element that displays the "EmployeeName" and "PhoneNumber" fields of each row in the data source would look like this:

```
<ItemTemplate>
   <%# DataBinder.Eval(Container, "DataItem.EmployeeName") %>
   <%# DataBinder.Eval(Container, "DataItem.PhoneNumber") %>
   <br>
</ItemTemplate>
```

   For details, see Data Access in Web Forms Pages.

The following example shows what a complete **Repeater** control definition might look like in HTML view. The **Repeater** control is specified to render as a table. The <table> element begins in the **HeaderTemplate** and ends in the **FooterTemplate**. (The Task List will report errors for this situation, but the errors can be safely ignored and the table will be correctly displayed when the application is run.) Within the body of the **Repeater** control, table cells are used to display columns from the data source. The **AlternatingItemTemplate** element is identical to the **ItemTemplate** item except that the background color for the table cells is different to create a banded effect.

```
<asp:Repeater id=Repeater1 runat="server" DataSource="<%# DataView1%>">
   <HeaderTemplate>
      <table width="100%" style="font: 8pt verdana">
      <tr style="background-color:DFA894">
         <th> First Name </th>
         <th> Last Name </th>
      </tr>
   </HeaderTemplate>
   <ItemTemplate>
      <tr>
         <td><%# DataBinder.Eval(Container, "DataItem.EmployeeName") %>
         </td>
         <td><%# DataBinder.Eval(Container,"DataItem.PhoneNumber") %>
         </td>
      </tr>
   </ItemTemplate>
   <AlternatingItemTemplate>
      <tr>
         <td bgcolor="lightblue">
         <%# DataBinder.Eval(Container, "DataItem.EmployeeName") %> </td>
         <td bgcolor="lightblue">
         <%# DataBinder.Eval(Container,"DataItem.PhoneNumber") %> </td>
      </tr>
   </AlternatingItemTemplate>
   <FooterTemplate> </table> </FooterTemplate>
</asp:Repeater>
```

The following example uses a label control to display values from a database. A division between values in the list is created using the separator template. Note that the value of the Text attribute of the **Label** control is contained in single quotation marks. Attribute values are normally enclosed in double quotation marks, but since the **DataBinder** call contains double quotation marks, the Text attribute value must be enclosed in single quotation marks.

```
<asp:Repeater id="Repeater1" runat="server" DataSource="<%# DataView1%>">
   <ItemTemplate>
      <asp:Label id=Label1 runat="server"
         Text='<%# DataBinder.Eval(Container, "DataItem.EmployeeName")%>'>
      </asp:Label>
   </ItemTemplate>
   <SeparatorTemplate>,</SeparatorTemplate>
</asp:Repeater>
```

Table, TableRow, and TableCell Web Server Controls

The **Table** Web server control creates a general-purpose table on a Web Forms page. Rows in the table are created as **TableRow** Web server controls, and cells within each row are implemented as **TableCell** Web server controls.

The following topics provide information that you will find useful in learning to work with the **Table**, **TableRow**, and **TableCell** controls.

In This Section

Introduction to the Table Web Server Control
Provides background information on the **Table**, **TableRow**, and **TableCell** controls, including how a **Table** control compares to other list Web server controls.

Web Forms Data Binding
Provides basic conceptual information about binding data to Web Forms.

Introduction to the Table Web Server Control

The Table Web server control allows you to create server-programmable tables on your Web Forms page. The TableRow and TableCell Web server controls provide a way to display the actual content for the **Table** control.

Comparing the Table Web Server Control to Other Table Elements

Tables are typically used not only to present tabular information, but as a way to format information on a Web page. There are a number of ways to create tables on your Web Forms page:

- HTML table You can add a <TABLE> element from the HTML tab of the Toolbox.
- HtmlTable **control** This is a <TABLE> HTML element that has been converted to an HTML server control by adding the `runat=server` attribute. You can program this control in server code. For details about HTML server controls, see Introduction to ASP.NET Server Controls.
- **Table Web Server control** A Web control that allows you to create and manipulate tables (for example, adding table rows and cells) using an object model that is consistent with other Web controls.

In general, you use a **Table** Web server control when you intend to add rows and cells (columns) to the table in code at run time. Although you can use it as a static table with predefined rows and columns, it's easier in that case to work with the HTML <TABLE> element.

The **Table** Web server control can be easier to program than the HtmlTable control because it offers an object model with typed properties that is consistent with other Web server controls. (The model is also consistent between the **Table**, **TableRow**, and **TableCell** controls.)

Comparing the Table Web Server Control to Other List Web Server Controls

Some of the functions you might accomplish with a **Table** Web server control can also be accomplished with the list Web server controls: the Repeater, DataList, and DataGrid controls. All of these controls render (or have the option to render) as HTML tables. For a discussion of the differences among these three list controls, see Controls for Displaying Lists On Web Pages.

The differences between the list controls and the **Table** control are these:

- The list controls are data-bound. The list controls work only against a data source, whereas the **Table** control can display any combination of HTML text and controls, whether or not they are data-bound.
- The list controls use templates to specify the layout of their elements. The **Table** control supports the **TableCell** child control, which you can fill as you would any HTML <TD> element.

Table Web Server Control Object Model

The **Table** control acts as a parent control for TableRow controls. The table supports a property called Rows that is a collection of **TableRow** objects. By managing this collection — adding or deleting items in it — you specify the rows for the table. The **TableRow** control in turn supports a collection called Cells of TableCell objects.

The content to be displayed in the table is added to the **TableCell** control. The cell has a **Text** property that you set to any HTML text. Alternatively, you can display controls in the cell by creating instances of, and adding controls to, the cell's **Controls** collection.

The parent **Table** control supports properties to control the appearance of the entire table, such as Font, BackColor, and ForeColor. The **TableRow** and **TableCell** controls support these properties as well, so you can specify the look of individual rows or cells, overriding the parent table appearance.

Binding Data to the Control

Although the **Table** control (unlike the list Web server controls; see above) is not inherently data bound, you can use it to display data from a database.

As with all Web server controls, you can bind any property of a **Table** control to a data source. However, the **Table** control does not support a property that you use to directly display data. Instead, you typically add **TableCell** controls to the table. You can then either bind the **Text** property of individual **TableCell** controls to data, or you can add data-bound controls (such as a **Label** or **TextBox** control) to the cell.

See Also

Adding Rows and Cells Dynamically to a Table Web Server Control |
Displaying Database Information Using a Table Web Server Control | Web Forms Data Binding | Web Server Controls Templates

Adding Table Web Server Controls to a Web Forms Page

Adding a **Table** Web server control consists of two steps: adding the table itself, and separately adding the rows and cells. You can add rows and columns at design time to create a static table, or you can add them at run time in code. For details about adding them at run time, see Adding Rows and Cells Dynamically to a Table Web Server Control.

To add a Table control to a Web Forms page

- Switch to **Design** view in the Web Forms Designer, and then drag a **Table** control from the **Web Forms** tab of the Toolbox onto the page.

  The table is initially displayed as a simple text control with no rows or columns.

To create a static table, you can add rows and cells at design time.

To add rows and cells to a Table Web server control at design time

1. Select the table, and then open the Properties window and click the ellipsis button (...) for the **Rows** property.

   The **TableRow Collection Editor** window is displayed.

2. Click **Add** to create a new row.

   A new row is added, and its properties are displayed in a grid on the right-hand side of the dialog box.

3. Optionally, set display characteristics for the new row by changing its font, color, and so on.

   > **Note** Settings you enter in the **TableRow Collection Editor** dialog box apply to only one row. To apply settings that apply to all rows, set properties for the table as a whole.

4. To add cells to the new row, make sure the row is selected in the **Members** list, and then click the ellipsis button (...) for the **Cells** property.

   The **TableCell Collection Editor** dialog box is displayed.

5. Click **Add** to create a new cell, and set its properties using the grid on the right-hand side of the dialog box. To display text in the cell, set its **Text** property.
6. Repeat Step 5 for each cell you want to add to a row. When you are finished adding cells to a row, click **OK** in the **TableCell Collection Editor** dialog box.
7. Repeat Steps 2 through 6 for each new row and its cells. When you are finished adding rows to the table, click **OK** in the **TableRow Collection Editor** dialog box.

   The **Table** control is displayed in **Design** view with placeholder characters for each row and cell that you have created.

Introduction to the Table Web Server Control | Adding Rows and Cells Dynamically to a Table Web Server Control | Displaying Database Information Using a Table Web Server Control | Table Class

Adding Rows and Cells Dynamically to a Table Web Server Control

It's common to add rows and cells to a **Table** Web server control at run time. The Table Web Server control is designed specifically for this task.

> **Note** To design a table visually in Design view, use an HtmlTable control. If you also need to programmatically manipulate the contents of the **HtmlTable** control, convert its rows and cells to HtmlTableRow and HtmlTableCell controls by setting their
> runat
> attribute to
> server
> . For details, see Converting HTML Server Controls to HTML Elements.

Rows in a **Table** Web server control are objects of type **TableRow**. The Rows property of the **Table** control supports a collection of **TableRow** objects. To add a row to the table, you add a **TableRow** object to this collection.

Similarly, the **TableRow** object has a Cells property that supports a collection of objects of type **TableCell**. You can add cells to a row by manipulating this collection.

To add rows and cells to a table dynamically

1. To add a row, create a new object of type TableRow:

```
' Visual Basic
Dim tRow As New TableRow()
Table1.Rows.Add(tRow)

// C#
TableRow tRow = new TableRow();
Table1.Rows.Add(tRow);
```

2. To add cells to the row, create one or more objects of type TableCell:

```
' Visual Basic
Dim tCell As New TableCell()
tRow.Cells.Add(tCell)

// C#
TableCell tCell = new TableCell();
tRow.Cells.Add(tCell);
```

3. Add content to the new cell. You can do this in several ways, as shown in the following table.

To add	Do this
Static text	Set the cell's Text property.
Controls	Declare an instance of the control and add it to the cell's **Controls** collection.
Both text and controls in the same cell	Declare the text by creating an instance of the LiteralControl class. Add it to the cell's **Controls** collection as you would other controls.

> **Note** By default, controls that you add dynamically to a Web Forms page are added to the page's view state. If you recreate controls with each round trip, this can result in unexpected behavior when the page is processed, because view state is restored before the controls are recreated. You can avoid problems by setting the EnableViewState property of the container control (for example, of the **Table** control) to **false**. For more information, see Adding Controls to a Web Forms Page Programmatically.

The following example shows you can add rows and cells to a **Table** control. The number of rows and columns is determined by what the user enters into two text boxes. Each cell displays the row and cell number as static text.

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles But
```

```
ton1.Click
   ' Total number of rows
   Dim rowCnt As Integer
   ' Current row count
   Dim rowCtr As Integer
   ' Total number of cells (columns)
   Dim cellCtr As Integer
   ' Current cell counter
   Dim cellCnt As Integer

   rowCnt = CInt(Textbox1.Text)
   cellCnt = CInt(Textbox2.Text)

   For rowCtr = 1 To rowCnt
      Dim tRow As New TableRow()
      For cellCtr = 1 To cellCnt
         Dim tCell As New TableCell()
         tCell.Text = "Row " & rowCtr & ", Cell " & cellCtr
         ' Add new TableCell object to row
         tRow.Cells.Add(tCell)
      Next
      ' Add new row to table
      Table1.Rows.Add(tRow)
   Next

End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e){
   // Total number of rows
   int rowCnt;
   // Current row count
   int rowCtr;
   // Total number of cells per row (columns)
   int cellCtr;
   // Current cell counter
   int cellCnt;

   rowCnt = int.Parse(TextBox1.Text);
   cellCnt = int.Parse(TextBox2.Text);

   for(rowCtr=1; rowCtr <= rowCnt; rowCtr++) {
      // Create new row and add it to the table.
      TableRow tRow = new TableRow();
      Table1.Rows.Add(tRow);
      for (cellCtr = 1; cellCtr <= cellCnt; cellCtr++) {
         // Create a new cell and add it to the row.
         TableCell tCell = new TableCell();
         tCell.Text = "Row " + rowCtr + ", Cell " + cellCtr;
         tRow.Cells.Add(tCell);
      }
   }
}
```

The following example is similar to the previous one, but displays static text and a HyperLink control in each cell. The **Hyperlink** control navigates to a mocked-up URL, passing a mock product ID. Because the sample mixes static text and controls, the static text is implemented as a **LiteralControl** object, which is added to the cell's **Controls** collection just like the **Hyperlink** control is.

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles But
ton1.Click
   ' Total number of rows
   Dim rowCnt As Integer
   ' Current row count
   Dim rowCtr As Integer
   ' Total number of cells (columns)
   Dim cellCtr As Integer
   ' Current cell counter
   Dim cellCnt As Integer

   rowCnt = CInt(TextBox1.Text)
   cellCnt = CInt(TextBox2.Text)

   For rowCtr = 1 To rowCnt
      Dim tRow As New TableRow()
      For cellCtr = 1 To cellCnt
         Dim tCell As New TableCell()
         ' Mock up a product ID
         Dim prodID As String
         prodID = rowCtr & "_" & cellCtr

         ' Create literal text as control
         Dim s As New LiteralControl()
         s.Text = "Buy: "
         tCell.Controls.Add(s)   ' Add to cell
         ' Create Hyperlink Web Server control and add to cell
         Dim h As New HyperLink()
         h.Text = rowCtr & ":" & cellCtr
         h.NavigateUrl = "http://www.microsoft.com/net"
         tCell.Controls.Add(h)
         ' Add cell to row
         tRow.Cells.Add(tCell) ' Add new TableCell object to row
      Next cellCtr
      Table1.Rows.Add(tRow) ' Add new row to table
   Next rowCtr
End Sub

// C#
public void Button1_Click (object sender, System.EventArgs e){
   // Total number of rows
   int rowCnt;
   // Current row count
   int rowCtr;
   // Total number of cells per row (columns)
   int cellCtr;
   // Current cell counter
   int cellCnt;

   rowCnt = int.Parse(TextBox1.Text);
   cellCnt = int.Parse(TextBox2.Text);

   for(rowCtr=1; rowCtr <= rowCnt; rowCtr++) {
      // Create new row and add it to the table.
      TableRow tRow = new TableRow();
      Table1.Rows.Add(tRow);
      for (cellCtr = 1; cellCtr <= cellCnt; cellCtr++) {
```

```
            // Create a new cell and add it to the row.
            TableCell tCell = new TableCell();
            tRow.Cells.Add(tCell);
            // Mock up a product ID.
            string prodID = rowCtr + "_" + cellCtr;

            // Add a literal text as control.
            tCell.Controls.Add(new LiteralControl("Buy: "));
            // Create Hyperlink Web Server control and add to cell
            System.Web.UI.WebControls.HyperLink h = new HyperLink();
            h.Text = rowCtr + ":" + cellCtr;
            h.NavigateUrl = "http://www.microsoft.com/net";
            tCell.Controls.Add(h);
        }
    }
}
```

Introduction to the Table Web Server Control | Displaying Database Information Using a Table Web Server Control | Table Class

Displaying Database Information Using a Table Web Server Control

It's possible to display database information using the **Table** Web server control.

> **Tip** For many applications, it is easier to display data-bound information in a table by using the Repeater, DataList, or DataGrid Web server controls.

In the most common scenario for displaying data in a **Table** Web server control, each row of the table represents a data row from the data source, and each cell of the table displays a single field from a row. Unlike the list controls (**Repeater**, **DataList**, and so on), the **Table** control does not have a mechanism for automatically iterating through the rows in a data source. Therefore, you must do this yourself.

For general details about data binding in Web server controls, see Web Forms Data Binding.

To display database information in a Table Web server control

1. Add a dataset to the page. For information on how to do this, see Walkthrough: Creating a Distributed Application, Walkthrough: Simple Data Access in a Windows Form, or Creating Typed Datasets with the Component Designer. For a discussion of options in creating datasets from database tables, see Introduction to ADO.NET Connection Design Tools, Introduction to Data Adapters, and Introduction to Datasets.
2. Add a row to the table for each row in the dataset, and then set the contents of each **TableCell** object in the row to the data to be displayed. Most often you set the cell's **Text** property to an expression that extracts data from a data source. It's also possible to include controls in a **TableCell** control and bind the controls to a source of data. For details about using controls to display information, see Adding Rows and Cells Dynamically to a Table Web Server Control.

   The following example illustrates one way to display data in a **Table** Web server control. The sample shows an event handler for a button. The method loops through the **DefaultView** object of a dataset, creating a **TableRow** control for each row in the dataset. The code then creates a **TableCell** control in each table row and sets its **Text** property to the "name" field of the current data row.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles Button1.Click
   Dim aDataView As DataView = authorData.Tables(0).DefaultView
   Dim aRow As DataRowView
   For Each aRow In aDataView
      Dim aTableRow As New TableRow()
      Dim aCell As New TableCell()
      aCell.Text = aRow.Item("last").ToString()
      aTableRow.Cells.Add(aCell)
      Table1.Rows.Add(aTableRow)
   Next
End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e)
{
   DataView aDataView = authorData.Tables[0].DefaultView;
   foreach( DataRowView aRow in aDataView)
   {
      TableRow aTableRow = new TableRow();
      TableCell aCell = new TableCell();
      aCell.Text = aRow["last"].ToString();
      aTableRow.Cells.Add(aCell);
      Table1.Rows.Add(aTableRow);
   }
}
```

Note Controls that you add dynamically to a Web Forms page do not automatically become part of the page's view state — neither the controls nor their values are saved when a page performs a round trip to the server. You are therefore responsible for saving the state of any dynamically-generated controls whose values you want to preserve. For details, see Introduction to Web Forms State Management.

Data Binding Single-Value Web Server Controls at Design Time
Gives directions for displaying data in a **TextBox** control.

Introduction to the TextBox Web Server Control

The TextBox Web server control provides a way for users to type information into a Web Form, including text, numbers, and dates. You can configure the **TextBox** Web server control in several ways:

Configuration	Description
Single-line	Users type information in a single line. You can optionally limit the number of characters that the control accepts.
Password	Like a single-line **TextBox** control, but the characters users type are masked with asterisks (*) to hide them. **Security Note** Using a **TextBox** control set for passwords can help ensure that other people will not be able to determine a user's password if they observe the user entering it. However, the password text entered is not encrypted in any way, and you should protect it as you would any other confidential data. For example, for maximum security when posting a form with a password in it, you might use secure sockets layer (SSL) and encryption. For more information, see Web Application Security at Run Time.
Multi-line	Users type information in a box that displays multiple lines and allows text wrapping.

Security Note User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

The **TextBox** control raises a TextChanged event when the user leaves the control. By default, the event is not raised immediately; instead, it is raised on the server when the Web Forms page is submitted. However, you can specify that the TextBox control should submit the page to the server as soon as the user leaves the field.

Note The **TextBox** Web server control does not raise an event each time the user enters a keystroke, only when the user leaves the control.

See Also

Adding Web Server Controls to a Web Forms Page | Introduction to Validating User Input in Web Forms | Setting Web Server Control Properties Programmatically | Customizing the Appearance of ASP.NET Server Controls Using Styles

Getting and Setting Values in TextBox Web Server Controls

You can get or set the value of a TextBox at run time.

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

To get or set values in the TextBox control

- Get or set the value of the control's Text property.

  The following example shows how you can read the value of one TextBox control (called `TextBox1`) and use it to set the value of another (`TextBox2`).

```
' Visual Basic
Public Sub Button1_Click(ByVal sender As Object, ByVal e As System.EventArgs) Handles But
ton1.Click
   Textbox2.Text = TextBox1.Text
End Sub

// C#
public void Button1_Click(object sender, System.EventArgs e)
{
   TextBox2.Text = TextBox1.Text;
}
```

See Also

ASP.NET Server Control Event Model | Setting Web Server Control Properties Programmatically | TextBox Class

Responding to Changes in a TextBox Web Server Control

When the user leaves a **TextBox** Web server control after entering information, the control raises an event that you can respond to.

> **Note** The **TextBox** Web server control does not raise an event each time the user enters a keystroke, only when the user leaves the control.

To respond to changes in the TextBox control

- Create an event handler for the **TextBox** control's TextChanged event.

  By default, the **TextChanged** event does not immediately cause the Web Forms page to be posted to the server. Instead, the event is raised in server code the next time the form is posted, as when a Button Web server control is clicked. To have the **TextChanged** event cause an immediate posting, set the **TextBox** control's AutoPostBack property to **true**.

  > **Note** The ability of a **TextBox** control to post to the server when it is checked requires that the browser support ECMAScript (JScript, JavaScript) and that scripting be enabled on the user's browser.

  The following example shows how you can respond to changes in the **TextBox** control. The code displays the contents of the control in a label.

  > **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

```
' Visual Basic
Public Sub TextBox1_TextChanged(ByVal sender As Object, ByVal e As System.EventArgs) Hand
les TextBox1.TextChanged
   Label1.Text = TextBox1.Text
End Sub

// C#
public void TextBox1_TextChanged(object sender, EventArgs e)
{
   Label1.Text = TextBox1.Text;
}
```

Setting a TextBox Web Server Control for Password Entry

A **TextBox** Web server control set for passwords hides a user's entry as it is being typed. Password text boxes can only be single-line text boxes.

> **Security Note** Using a **TextBox** control set for passwords can help ensure that other people will not be able to determine a user's password if they observe the user entering it. However, the password text entered is not encrypted in any way, and you should protect it as you would any other confidential data. For example, for maximum security when posting a form with a password in it, you might use secure sockets layer (SSL) and encryption. For more information, see Web Application Security at Run Time.

To create a password textbox

1. Set the **TextBox** control's TextMode property to **Password**. In code, text modes are set using the TextBoxMode enumeration.
2. Set the size of the control by setting its Width property to a value in pixels or its Columns property to the number of characters to display. If you set both properties, **Width** takes precedence.

   > **Note** The **Width** property does not work in browsers that do not support CSS styles.

3. Optionally, you can limit the number of characters the user is allowed to enter by setting the control's MaxLength property. If the users exceed this number of characters, the control stops accepting more.

   > **Note** You might not want to set the **MaxLength** property, because it can be of use to unauthorized users who are trying to guess the password.

Specifying Multiline Input for a TextBox Web Server Control

A multi-line **TextBox** control allows users to type information into a box that supports word wrap and vertical and horizontal scrolling.

To create a multiline TextBox Web server control

1. Set the **TextBox** control's TextMode property to **MultiLine**. In code, text modes are set using the TextBoxMode enumeration.
2. Set the size of the control by setting the following properties:

   - Width to a value in pixels, or Columns to the number of characters to display.
   - Height to a value in pixels, or Rows to the number of rows.

     Note The **Height** and **Width** property do not work in browsers that do not support CSS styles.

   Setting these properties does not limit the number of characters or rows the user can enter, only how many will display. The control always displays a vertical scrollbar. **Height** and **Width** take precedence over **Rows** and **Columns**.

   Tip By default, a multi-line **TextBox** control includes a vertical scrollbar. To hide the scrollbar, include the style attribute
   overflow: hidden
   . For example, in HTML view, the declarative syntax for the control might look as follows:

```
<asp:TextBox id="TextBox1" style="Z-INDEX: 101; LEFT: 56px; OVERFLOW: hidden; POSITION: a
bsolute; TOP: 72px" runat="server" TextMode="MultiLine"></asp:TextBox>
```

3. Set word-wrap behavior by setting the control's Wrap property. If true, text wraps automatically (without embedding carriage-return/linefeed characters). If false, the text does not wrap and the user must press ENTER to start a new line, which embeds a carriage-return/linefeed character. Setting **Wrap** to **false** causes the control to display a horizontal scrollbar.

   Note The MaxLength property has no effect in a multi-line textbox.

Validation Web Server Controls

There is a set of Web server controls that you can use to validate input on your Web Forms pages. These controls ensure that the information that a user has provided matches the requirements of your application. There are standard controls for different types of validation, such as range checking or pattern matching, and a custom control that you can use to establish your own validation criteria. For more information on validation, see Introduction to Validating User Input in Web Forms.

The validation controls listed below appear on the **Web Forms** tab of the Toolbox.

In the Visual Basic and Visual C# Documentation

RequiredFieldValidator
Ensures that the user does not skip a required field when entering data on a Web Forms page. For details, see Validating Required Entries for ASP.NET Server Controls.

CompareValidator
Compares a user's entry against a constant value, against the property value of another control, or against a database value. For details, see Validating Against a Specific Value for ASP.NET Server Controls or Validating Against a Data Type for ASP.NET Server Controls.

RangeValidator
Ensures that a user's entry is between specified upper and lower bounds. For details, see Validating Against a Range of Values for ASP.NET Server Controls.

RegularExpressionValidator
Ensures that a user's entry matches a pattern defined by a regular expression. For details, see Validating Against Patterns for ASP.NET Server Controls.

CustomValidator
Ensures that a user's entry matches validation logic you create yourself. For details, see Validating with a Custom Function for ASP.NET Server Controls.

ValidationSummary
Provides a central location to display validation error messages. For details, see Controlling Validation Error Message Display for ASP.NET Server Controls.

XML Web Server Control

An **XML** Web server control reads XML and writes it into a Web Forms page at the location of the control. If an XSL Transformations (XSLT) is applied to the XML, the resulting transformed output will be rendered in the Web Forms page.

The following topics provide information that you will find useful in learning to work with the XML Web server control.

XML in Visual Studio
Introduces topics about XML as it relates to various Visual Studio feature areas, including data, XML Web services, Web Forms, and reference materials.

Introduction to the XML Web Server Control

You can use the XML Web server control to write an XML document, or the results of an XSL Transformations (XSLT), into a Web page. The XML output appears in the Web page at the location of the control. For more information on XML and XSLT, see XML (Extensible Markup Language) in the Microsoft XML SDK documentation.

The XML and the XSLT information can be in external documents, or you can include the XML inline. There are two ways to reference external documents using property settings in the **XML** Web server control. You can provide a path to the XML document in the control tag, or you can load the XML and XSLT documents as objects and then pass them to the control. If you prefer to include the XML inline, write it between the opening and closing tags of the control.

Adding XML Web Server Controls to a Web Forms Page

Add **XML** Web server controls to the place in the page where you want the output to appear.

To add an XML Web server control to a Web Forms page

1. In Design view, drag an **XML** control from the **Web Forms** tab of the Toolbox onto the page.
2. Load the XML data that you want to display into the control by setting the **Document** or **DocumentSource** property, or by putting the XML between the control's opening and closing tags. For details, see Loading XML Data in the XML Web Server Control.

   Note You need to be sure that when your application runs, it has sufficient permissions to read the XML file. For details, see Access Permissions for Web Applications.

To add a control to a Web Forms page programmatically

1. Create an instance of the control and set its properties:

```
' Visual Basic
Dim myXML As System.Web.UI.WebControls.Xml = _
      New System.Web.UI.WebControls.Xml()
myXML.DocumentSource = "SourceDoc.xml"
myXML.TransformSource = "SourceTrans.xsl"

// C#
System.Web.UI.WebControls.Xml myXML =
      new System.Web.UI.WebControls.Xml();
myXML.DocumentSource = "SourceDoc.xml";
myXML.TransformSource = "SourceTrans.xsl";
```

2. Add the new control to the **Controls** collection of a container already on the page:

```
' Visual Basic
PlaceHolder1.Controls.Add(myXML)

// C#
PlaceHolder1.Controls.Add(myXML);
```

   Note Controls that you add dynamically to a Web Forms page do not automatically become part of the page's view state — neither the controls nor their values are saved when a page performs a round trip to the server. You are therefore responsible for saving the state of any dynamically-generated controls whose values you want to preserve. For details, see Introduction to Web Forms State Management.

Introduction to the XML Web Server Control | Transforming XML Data in the XML Web Server Control | Walkthrough: Displaying an XML Document in a Web Forms Page using Transformations

Loading XML Data in the XML Web Server Control

There are three ways to load XML data into the **XML** Web server control.

- Provide a path to an external XML document, using the **DocumentSource** property.
- Load an XML document as an object and pass it to the control, using the **Load** method in the **Page_Load** event and assigning the document to the **Document** property of the **XML** control.
- Include the XML content inline, between the opening and closing tags of the control.

To provide a path to an external XML document

1. Add an **XML** control to the Web Forms page. For details, see Adding XML Web Server Controls to a Web Forms Page.
2. Set the **DocumentSource** property of the control to the path to the XML source document.

   > **Note** You need to be sure that when your application runs, it has sufficient permissions to read the XML file. For details, see Access Permissions for Web Applications.

   The XML document will be written directly to the output stream unless you also specify the **TransformSource** property. **TransformSource** must be a valid XSL Transformations document, which will be used to transform the XML document before its contents are written to the output stream. The following example shows how to refer to source documents by using a relative path.

```
<body>
    <h3>XML Example</h3>
    <form runat=server>
        <asp:Xml id="Xml1" DocumentSource="MySource.xml"
            TransformSource="MyStyle.xsl" runat="server" />
    </form>
</body>
```

To load an XML document as an object and pass it to the control

1. Add an **XML** control to the Web Forms page. For details, see Adding XML Web Server Controls to a Web Forms Page.
2. On the **View** menu, click **Code**. In the Code Editor, find the **Page_Load** procedure.
3. Add code to load the XML source document, and assign the source to the **Document** property of the control. For example:

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
      ByVal e As System.EventArgs) Handles MyBase.Load
   Dim doc As System.Xml.XmlDocument = New System.Xml.XmlDocument()
   doc.Load(Server.MapPath("MySource.xml"))
   Dim trans As System.Xml.Xsl.XslTransform = _
      New System.Xml.Xsl.XslTransform
   trans.Load(Server.MapPath("MyStyle.xsl"))
   Xml1.Document = doc
   Xml1.Transform = trans
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
    System.Xml.XmlDocument doc = new System.Xml.XmlDocument();
    doc.Load(Server.MapPath("MySource.xml"));
    System.Xml.Xsl.XslTransform trans = new
       System.Xml.Xsl.XslTransform();
    trans.Load(Server.MapPath("MyStyle.xsl"));
    Xml1.Document = doc;
    Xml1.Transform = trans;
}
```

To include the XML content inline

1. Add an **XML** control to the Web Forms page. For details, see Adding XML Web Server Controls to a Web Forms Page.
2. In HTML view, find the `<asp:Xml>` and `</asp:Xml>` tags.
3. Add your XML code between these two tags. For example:

```
<asp:xml TransformSource="MyStyle.xsl" runat=server>
    <clients>
        <name>Frank Miller</name>
        <name>Judy Lew</name>
    </clients>
</asp:xml>
```

Introduction to the XML Web Server Control | Adding XML Web Server Controls to a Web Forms Page |
Transforming XML Data in the XML Web Server Control |
Walkthrough: Displaying an XML Document in a Web Forms Page using Transformations

Transforming XML Data in the XML Web Server Control

An XSL transformations (XSLT) style sheet (.xslt or .xsl file) is used to transform the content of a source XML document into a presentation that is tailored specifically to a particular user, media, or client. For an overview, see the XSLT Developer's Guide. There are two ways to transform XML data in the **XML** Web server control:

- Point to an external XSLT file, which will automatically apply the transformation to the XML document.
- Apply a transformation that is an object of type XslTransform to the XML document.

Both methods have the same results, and your choice is dependent primarily on what is most convenient in your application. If the transformation is in the form of an .xsl or .xslt file, it is easy to load the file. If the transformation is in the form of an object — perhaps it is being passed to your application by another process — then you can apply it as an object.

> **Note** The **XslTransform** class also allows you to load an .xsl or .xslt file into the instance of the transformation.

To apply a transformation from a file

1. Add an XML control to the Web Forms page. For details, see Adding XML Web Server Controls to a Web Forms Page.
2. Set the **XML** control's TransformSource property to the path to the XSLT document.

   > **Note** You need to be sure that when your application runs, it has sufficient permissions to read the XML file. For details, see Access Permissions for Web Applications.

   The following example shows how you can apply a transformation from a file to an **XML** control called `Xml1`.

```
'Visual Basic
Xml1.TransformSource = "mystyle.xsl"

//C#
Xml1.TransformSource = "mystyle.xsl";
```

To apply a transformation from an XslTransform object

1. Create an instance of the XslTransform class.
2. Set the **XML** control's Transform property to the instance of the transformation.

   The following example shows how you can create an instance of the transformation class and use it to apply the transformation to an object. In this example, both the XML document and the transformation are read from files, but in a real application, both objects might come from another component. The transformation is applied as soon as the page loads.

```
'Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
      ByVal e As System.EventArgs) Handles MyBase.Load
   Dim doc As System.Xml.XmlDocument = New System.Xml.XmlDocument()
   doc.Load(Server.MapPath("MySource.xml"))
   Dim trans As System.Xml.Xsl.XslTransform = _
      New System.Xml.Xsl.XslTransform
   trans.Load(Server.MapPath("MyStyle.xsl"))
   Xml1.Document = doc
   Xml1.Transform = trans
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
    System.Xml.XmlDocument doc = new System.Xml.XmlDocument();
    doc.Load(Server.MapPath("MySource.xml"));
    System.Xml.Xsl.XslTransform trans = new
       System.Xml.Xsl.XslTransform();
```

```
        trans.Load(Server.MapPath("MyStyle.xsl"));
        Xml1.Document = doc;
        Xml1.Transform = trans;
    }
```

Loading XML Data in the XML Web Server Control |
Walkthrough: Displaying an XML Document in a Web Forms Page using Transformations

Walkthrough: Displaying an XML Document in a Web Forms Page using Transformations

As more and more information becomes available in the format of XML documents, you will find it increasingly likely that you will need to be able to work with these documents. This walkthrough illustrates how you can easily display information on a Web Forms page from a "non-structured" XML document — that is, an XML document that does not represent relational data.

XML and XSL in Web Forms Pages

Information in an XML file is "raw," containing only the data and no indication about how to format it, display it, and so on. To display XML information in a Web Forms page, you need to provide formatting and display information — for example, you need to provide the <TABLE> tags, <P> tags, or whatever you want to use to display the information. In addition, you must provide instructions for how the data from the XML file fits into these tags. For example, should each element in the XML file be displayed as a table row?

One way to provide these instructions is to create a Web Forms page and then use code to parse the XML file and fill the data into the appropriate HTML tags. However, this is a somewhat tedious and inflexible way to do so. (On the other hand, it is also a very powerful way that gives you precise programmatic control over the XML file.)

XSL Transformations

A far better way is to use the XSL transformation language and create "transformations," or XSL files. An XSL transformation contains this information:

- A template — basically, an HTML page with the appropriate tags — that specifies how the XML information should be displayed.
- XSL processing instructions, which specify exactly how the information from the XML file fits into the template.

You can define multiple transformations and then apply them to the same XML file. By doing so, you can use the XML information different ways, displaying it differently, selecting different data from the XML file, and so on.

Once you have XSL transformations, you need to apply them to the XML file — that is, you process the XML file by transforming it according to one of the XSL files. The output is a new file with the XML information formatted according to the transformation file.

Again, this is a process you can perform programmatically. However, you can also take advantage of the **XML** Web server control. (For an overview see XML Web Server Control.) This control works as a placeholder on your Web Forms page. You can set its properties to a specific XML file and XSL transformation, and when the page is processed, the control reads the XML, applies the transformation, and displays the results.

For more information about XSL, see XSLT Transformations with the XslTransform Class.

Goals of the Walkthrough

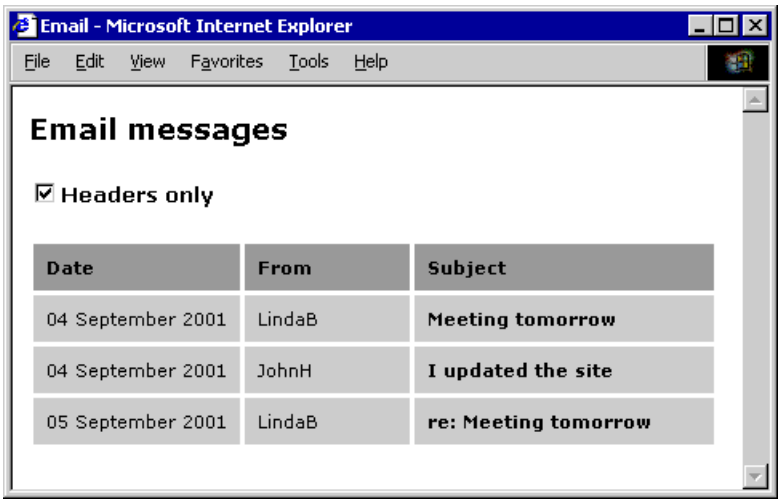
This walkthrough will illustrate how to use the **XML** Web server control to display XML information using XSL transformations. The scenario is simple. You will have the following:

- An XML file containing several fictional e-mail messages.
- Two XSL transformations. One displays only the date, sender, and subject of the e-mail messages. The other displays the entire e-mail message.

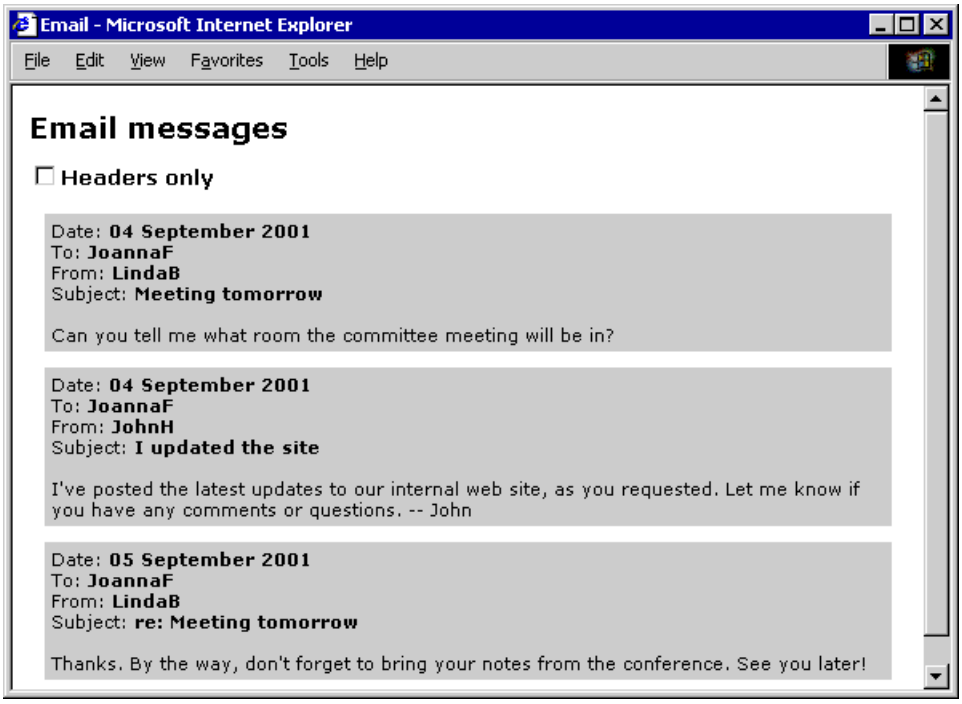
> **Note** All of these files are provided as part of the walkthrough.

You will create a Web Forms page that allows users to display the XML information two different ways. The page contains a "Headers only" check box that is checked by default; the default transformation, therefore, is the one that displays only the e-mail message headers. If users clear the check box, the XML information is redisplayed with the complete e-mail messages.

When the page displays only the headers, it might look something like the following:



When users clear the check box, the page changes to look something like this:



In order to complete this walkthrough, you will need sufficient permissions to be able to create ASP.NET Web application projects on the computer where your Web server is.

As part of the walkthrough, you will do the following:

- Create a new Web application project and Web Forms page.
- Add the XML file and the two XSL transformation files to the project.
- Add an **XML** Web server control to the Web Forms page and set it to display the XML file and a transformation.
- Add controls and code to allow the user to change the transformation applied to the XML file.

Creating the Project and Form

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, the name of the server, and the name of your project. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

> **Tip** If you have trouble creating a Web application project, see Web Access Failed Dialog Box.

Adding the XML File and XSL Transformations

The walkthrough scenario assumes that you are working with an existing XML file and two existing XSL transformation files. In a real application, you would create them yourself or get them from some source (perhaps another application). To save you the trouble of having to create or acquire these files, they are included as part of the walkthrough. The following steps (which would not be part of a real application) make these files available so you can continue with the walkthrough.

To add the XML file to your project

1. In Solution Explorer, right-click the name of your project, point to **Add**, then choose **Add New Item**.

   The **Add New Item** dialog box is displayed.

2. In the **Templates** pane, choose **XML File**.
3. In the Name box, change the name of the XML file to **Emails.xml**.

   > **Note** You can name the XML file anything you like. If you use a different name, make a note of it so you can use your name as appropriate later.

   The XML editor opens with a new XML file in it with an XML directive at the top.

4. Select the XML directive (and anything else in the file) and delete it.
5. Copy the following XML information and paste it into the file using the **Paste As HTML** command:

```
<?xml version="1.0" ?>
<MESSAGES>
   <MESSAGE id="101">
      <TO>JoannaF</TO>
      <FROM>LindaB</FROM>
      <DATE>04 September 2001</DATE>
      <SUBJECT>Meeting tomorrow</SUBJECT>
      <BODY>Can you tell me what room the committee meeting will be in?</BODY>
   </MESSAGE>
   <MESSAGE id="109">
      <TO>JoannaF</TO>
      <FROM>JohnH</FROM>
      <DATE>04 September 2001</DATE>
      <SUBJECT>I updated the site</SUBJECT>
      <BODY>I've posted the latest updates to our internal web site, as you requested. Le
t me know if you have any comments or questions. -- John
      </BODY>
   </MESSAGE>
   <MESSAGE id="123">
      <TO>JoannaF</TO>
      <FROM>LindaB</FROM>
      <DATE>05 September 2001</DATE>
      <SUBJECT>re: Meeting tomorrow</SUBJECT>
      <BODY>Thanks. By the way, do not forget to bring your notes from the conference. Se
e you later!</BODY>
   </MESSAGE>
</MESSAGES>
```

6. Save the file and close it.

Next you will add two XSL transformations to your project.

To add XSL transformations to your project

1. In Solution Explorer, right-click the name of your project, point to **Add**, then choose **Add New Item**.

   The **Add New Item** dialog box appears.

2. In the **Templates** pane, choose **XSLT File**.
3. In the **Name** box, change the name of the file to **Email_headers.xslt**.

   > **Note** You can name the XML file anything you like. If you use a different name, make a note of it so you can use your name as appropriate later.

   The XML editor opens with some XSLT directives and elements in it.

4. Select everything in the file and delete it.
5. Copy the following and paste it into the file using the **Paste As HTML** command:

```
<?xml version='1.0'?>
<xsl:stylesheet xmlns:xsl="http://www.w3.org/1999/XSL/Transform" version="1.0">
<xsl:template match="/">
<HTML>
<BODY>
<TABLE cellspacing="3" cellpadding="8">
   <TR bgcolor="#AAAAAA">
      <TD class="heading"><B>Date</B></TD>
      <TD class="heading"><B>From</B></TD>
      <TD class="heading"><B>Subject</B></TD>
   </TR>
   <xsl:for-each select="MESSAGES/MESSAGE">
   <TR bgcolor="#DDDDDD">
       <TD width="25%" valign="top">
         <xsl:value-of select="DATE"/>
       </TD>
      <TD width="20%" valign="top">
         <xsl:value-of select="FROM"/>
      </TD>
       <TD width="55%" valign="top">
         <B><xsl:value-of select="SUBJECT"/></B>
      </TD>
   </TR>
   </xsl:for-each>
</TABLE>
</BODY>
</HTML>
</xsl:template>
</xsl:stylesheet>
```

   > **Note** You can adjust this template as you like; for example, you might change colors, font sizes, styles, or other features.

6. Save the file and close it.
7. Repeat Steps 1 through 4, but this time name the file **Email_all.xslt**.
8. Paste the following into the **Email_all.xslt** file using the **Paste As HTML** command:

```
<?xml version='1.0'?>
<xsl:stylesheet xmlns:xsl="http://www.w3.org/1999/XSL/Transform" version="1.0">
<xsl:template match="/">
<HTML>
<BODY>
<FONT face="Verdana" size="2">
<TABLE cellspacing="10" cellpadding="4">
   <xsl:for-each select="MESSAGES/MESSAGE">
   <TR bgcolor="#CCCCCC">
```

```
    <TD class="info">
          Date: <B><xsl:value-of select="DATE"/></B><BR></BR>
          To: <B><xsl:value-of select="TO"/></B><BR></BR>
          From: <B><xsl:value-of select="FROM"/></B><BR></BR>
          Subject: <B><xsl:value-of select="SUBJECT"/></B><BR></BR>
          <BR></BR><xsl:value-of select="BODY"/>
        </TD>
    </TR>
    </xsl:for-each>
  </TABLE>
  </FONT>
  </BODY>
  </HTML>
  </xsl:template>
  </xsl:stylesheet>
```

Note You can adjust this template as you like; for example, you might change colors, font sizes, styles, or other features.

9. Save the file and close it.

Adding the XML Control to the Web Forms Page

Now that you have an XML file and two transformations, you can use them to display information in a Web Forms page. You do so using an **XML** Web server control.

When you are working with the **XML** control, it is easier to work in flow layout rather than grid layout, because you cannot use absolute positioning to specify the location of the XML control on the page. For more information, see pageLayout Property.

To set flow mode

1. Right-click the empty page and choose **Properties**.
2. Set the **Page Layout** value (**pageLayout** property) to **FlowLayout**.

Now you can add controls to the page.

To add an XML control

1. Open or move to the Web Forms page created by default when you created you Web application project.
2. From the **Web Forms** tab of the Toolbox, drag an **XML** control onto the page.

   A gray box representing the XML control is added to the top left corner of the page.

3. Select the control, and in the Properties window, set the following properties:

Property	Setting
DocumentSource	Emails.xml
TransformSource	Email_headers.xslt

   This will cause the **XML** control to display only the e-mail message headers by default.

Adding Controls to Change Transformations

In this walkthrough, you will use a check box to allow users to switch between transformations. By default, the **XML** control applies a transformation that displays only the e-mail message headers.

To add a check box to apply a different transformation

1. Select the **XML** control, press the BACKSPACE key, and press the ENTER key a few times to make space above the **XML** control.
2. From the **Web Forms** tab of the Toolbox, drag a **CheckBox** control onto the form above the **XML** control.
3. Set the following properties of the **CheckBox** control:

Property	Setting
Text	Headers only

Checked	**True**
AutoPostBack	**True**. This causes the form to be posted and processes as soon as the user clicks the box.

4. Double-click the check box.
5. The Code Editor opens with a skeleton handler for the **CheckBox** control's **CheckChanged** event.
6. Add code that switches transformations between **Email_headers.xslt** and **Email_all.xslt** depending on the state of the check box. The entire **CheckChanged** handler should look like the following:

```
' Visual Basic
Private Sub CheckBox1_CheckedChanged(ByVal sender As System.Object, ByVal e As System.Eve
ntArgs) Handles CheckBox1.CheckedChanged
   If CheckBox1.Checked Then
      Xml1.TransformSource = "email_headers.xslt"
   Else
       Xml1.TransformSource = "email_all.xslt"
   End If
End Sub

// C#
private void CheckBox1_CheckedChanged(object sender, System.EventArgs e)
{
   if (CheckBox1.Checked)
   {
      Xml1.TransformSource = "email_headers.xslt";
   }
   else
   {
      Xml1.TransformSource = "email_all.xslt";
   }
}
```

Testing

You can now see the transformations in action.

To test the transformations

1. Run the Web Forms page.

   By default, you will see the date, sender, and subject line of the e-mail messages.

2. Clear the **Headers only** check box.

   The e-mail messages are redisplayed, this time with a different layout and complete text.

Next Steps

This walkthrough has illustrated only the basics of how to work with an XML document and transformations. In a real application, you will often need to work with the XML document in more depth. The following are suggestions for further investigation:

- **Creating more sophisticated transformations** In this walkthrough, you have seen only one example of how you can use transformations. XSL is a powerful language, with sophisticated support not just for creating HTML pages, but also for virtually any kind of transformation from XML to another structure.For more details, see the Microsoft XSLT Developer's Guide.
- **Applying transformations programmatically** In this walkthrough, you took advantage of the **XML** Web server control to do the work of applying transformations to the raw XML data. You might find it useful in your application to do this work yourself (perhaps because it is impractical in your application to use an **XML** control). For details, see XSLT Transformations with the XslTransform Class.
- **Writing XML documents (instead of simply reading them)** The **XML** control makes it easy to display the contents of an XML file in a Web Forms page. However, you might want to create or amend XML files yourself. For details, see Employing XML in the .NET Framework.
- **Understanding security issues** Learn about the security issues associated with Web Forms. For details, see

Overview of Web Application Security Threats.

Simple HTML Controls

This section covers controls that are available on the **HTML** tab of the Toolbox. These HTML controls can be added to HTML pages or to Web Forms pages.

By default, HTML elements on a Web Forms page are not available to the server; they are treated as opaque text that is passed through to the browser. However, by converting HTML elements to HTML server controls, you expose them as elements you can program in server-based code. For an overview of how HTML elements can be exposed to the server so that you can program them, see Introduction to ASP.NET Server Controls.

In This Section

HTML Div Controls
Contains links to information on the DIV element and gives related information on programming it.
HTML Horizontal Rule Control

HTML Div Controls

Three controls based on the HTML DIV element are available on the HTML tab of the Toolbox:

- Flow Layout Panel control. Provides an area for flow (top to bottom) layout within a page configured for grid (x and y) layout.
- Grid Layout Panel control. Provides an area for grid layout (x and y) within a page configured for flow (top to bottom) layout.

  Note For details about flow and grid layout, see Positioning HTML Elements in Design View.

- Label control

  Note Dynamic HTML also includes an element named LABEL; it works only in Internet Explorer.

For a complete list of elements, see HTML Elements.

HTML controls added to an HTML page in Visual Studio are simply HTML elements with certain attributes already set.

The same is true for HTML controls added to a Web Forms (.aspx) page. By default, HTML elements on a Web Forms page are not available to the server; they are treated as opaque text that is passed through to the browser. However, by converting HTML elements to HTML server controls, you expose them as elements you can program in server-based code. For an overview of how HTML elements can be exposed to the server so that you can program them, see Introduction to ASP.NET Server Controls. For a list of these controls see HTML Server Controls.

HTML Input Controls

Several controls based on the HTML INPUT element are available on the HTML tab of the Toolbox:

- Button control: INPUT type=button Element
- CheckBox control: INPUT type=checkbox Element
- File Field control: INPUT type=file Element
- Hidden control: INPUT type=hidden Element
- Password control: INPUT type=password Element
- Radio Button control: INPUT type=radio Element
- Reset Button control: INPUT type=reset Element
- Submit Button control: INPUT type=submit Element
- Text Field control: INPUT type=text Element

For a complete list of elements, see HTML Elements.

> **Security Note** User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

HTML TITLE Element

Contains the title of the HTML document.

The TITLE element can be used only within the HEAD element. Any text between the opening and closing TITLE tags appears in the title bar of the browser.

For full details on this HTML element, see TITLE Element.

Directives for Web Forms Pages

Directives specify settings used by the page and user-control compilers when they process ASP.NET Web Forms page (.aspx) and user control (.ascx) files.

ASP.NET treats any directive block (<%@ %>) that does not contain an explicit directive name as an **@ Page** directive (for a page) or as an **@ Control** directive (for a user control).

For syntax information and descriptions of the attributes available for each directive, use the links that follow.

@ Page
: Defines page-specific attributes used by the ASP.NET page parser and compiler. Can only be included in .aspx files.

@ Control
: Defines control-specific attributes used by the ASP.NET page parser and compiler. Can only be included in .ascx files (user controls).

@ Assembly
: Declaratively links an assembly to the current page or user control.

@ Implements
: Declaratively indicates that a page or user control implements a specified .NET Framework interface.

@ Import
: Explicitly imports a namespace into a page or user control.

@ OutputCache
: Declaratively controls the output caching policies of a page or user control.

@ Reference
: Declaratively links a page or user control to the current page or user control.

@ Register
: Associates aliases with namespaces and class names, which allows user controls and custom server controls to be rendered when included in a requested page or user control.

Introduction to Web User Controls

The ASP.NET server controls provide a great deal of functionality, but they cannot cover every situation. Web user controls enable you to easily define controls as you need them for your applications, using the same programming techniques that you use to write Web Forms pages. You can even convert a Web Forms page into a Web user control with a few modifications. (For details see Walkthrough: Converting a Web Forms Page to a User Control.) To make sure that a user control cannot be run as a standalone Web Forms page, user controls are identified by the file name extension .ascx.

> **Note** Web user controls are not to be confused with Web custom controls. For more information, see Recommendations for Web User Controls vs. Web Custom Controls.

User Control Structure

A Web user control is similar to a complete Web Forms page, with both a user interface page and a code-behind file. The user interface page differs from an .aspx file in these ways:

- The extension must be .ascx.
- The user control does not have <HTML>, <BODY>, and <FORM> elements in it (these elements must be in the hosting page).

In every other way, a user control is like a Web Forms page. You can use the same HTML elements and Web controls on a user control that you do on a standard Web Forms page. For example, if you are creating a user control to use as a toolbar, you can put a series of Button Web server controls onto the control and create event handlers for the buttons.

Creating Web User Controls | Adding User Controls to a Web Forms Page | Introduction to Web Custom Controls | Recommendations for Web User Controls vs. Web Custom Controls | Walkthrough: Creating a Web User Control

Creating Web User Controls

You design Web user controls in much the same way that you design Web Forms pages. You can use the same HTML elements and Web controls on a user control that you do on a standard Web Forms page. However, the user control does not have <HTML>, <BODY>, and <FORM> elements in it, and the file name extension must be .ascx.

To create a Web Forms user control

1. Create a Web project. For details, see Creating Web Projects.
2. On the **Project** menu, click **Add Web User Control**. Change the name as desired and click **Open** to open the control in the designer.
3. Add text and controls to the design surface. Any controls that you want to be able to access programmatically must be Web Forms server controls or HTML server controls.
4. Use the Web Forms Designer to set properties and create any code required for your control.

The following example shows a simple user control that you might use as a menu. The four menu choices are implemented as Hyperlink Web server controls.

```
<!-- Visual Basic -->
<%@ Control Language="vb" AutoEventWireup="false"
    Codebehind="menu.ascx.vb" Inherits="myProj.menu"
    TargetSchema="http://schemas.microsoft.com/intellisense/ie5"%>
<P>
<asp:HyperLink id="lnkLogin" runat="server"
    NavigateURL="Login.aspx">Login</asp:HyperLink>
  |
<asp:HyperLink id="lnkAddToCart" runat="server"
   NavigateURL="Cart.aspx">Add to Cart</asp:HyperLink>
  |
<asp:HyperLink id="lnkTechSupport" runat="server"
   NavigateURL="TechSupport.aspx">Technical Support</asp:HyperLink>
  |
<asp:HyperLink id="lnkAbout" runat="server"
   NavigateURL="AboutUs.aspx">About Us</asp:HyperLink>
</P>

<!-- C# -->
<%@ Control Language="c#" AutoEventWireup="false"
    Codebehind="menu.ascx.cs" Inherits="myProj.menu"
    TargetSchema="http://schemas.microsoft.com/intellisense/ie5"%>
<P>
<asp:HyperLink id="lnkLogin" runat="server"
   NavigateURL="Login.aspx">Login</asp:HyperLink>
  |
<asp:HyperLink id="lnkAddToCart" runat="server"
   NavigateURL="Cart.aspx">Add to Cart</asp:HyperLink>
  |
<asp:HyperLink id="lnkTechSupport" runat="server"
   NavigateURL="TechSupport.aspx">Technical Support</asp:HyperLink>
  |
<asp:HyperLink id="lnkAbout" runat="server"
   NavigateURL="AboutUs.aspx">About Us</asp:HyperLink></P>
```

Introduction to Web User Controls | Adding User Controls to a Web Forms Page | Introduction to Web Custom Controls | Recommendations for Web User Controls vs. Web Custom Controls | Walkthrough: Creating a Web User Control

Adding User Controls to a Web Forms Page

You can add a Web user control to a Web Forms page in Design view by simply dragging the control from Solution Explorer and dropping it where you want it to appear in the page. The Web Forms Designer automatically adds an @ Register directive and a tag for the control to the page. From that point, the control becomes part of the page and is rendered when the page is processed. Also, the control's public properties, events, and methods are exposed to the page and can be worked with programmatically. You can also add user controls to a page programmatically.

> **Note** The user control must be in the same project as the Web Forms page.

To add a user control to a Web Forms page

1. In the Web Forms Designer, open the Web Forms page you want to add the control to, and make sure that the page is in Design View.
2. Select the user control's file in Solution Explorer, and drag it onto the page.

To add a user control to a Web Forms page in HTML view

1. In the Web Forms Designer, open the Web Forms page you want to add the control to, and then switch to HTML view.
2. At the top of the page, before the <HTML> tag, add a directive that registers the control so it will be recognized when the page is processed. You use the directive to associate a name and a namespace with the Web user control by specifying **TagPrefix**, **TagName**, and **Src** location values. For example:

   ```
   <%@ Register TagPrefix="uc1" TagName="menu" Src="menu.ascx" %>
   ```

   Put the directive in its own line. If there are no other directives, make it the first line in the file.

   The values for each attribute are listed in the following table.

Attribute	Description
TagPrefix	The TagPrefix determines a unique namespace for the user control, so that if multiple user controls on the page happen to have the same name, they can be differentiated from each other. This will be the prefix to the control's name (such as <myNameSpace:xxx>) in the tag.
TagName	The TagName is the name for the user control. This name is used in conjunction with the tag prefix to uniquely identify the namespace for your control, as in the following prefix:tagname element: <myNameSpace:myUserControl ... />
Src	The Src attribute is the virtual path to the user control, for example "UserControl1.ascx" or "/MyApp/Include/UserControl1.ascx".

3. In the <BODY> portion of the file, create a tag for your control where you want the control to appear. Use the TagPrefix and TagName you registered in Step 2. Give your control an ID and set the attribute runat=server, as in the following example:

   ```
   <uc1:menu id="Menu1" runat="server"/>
   ```

4. If your control has properties that you can set at design time, optionally set them by declaring their values in the tag:

   ```
   <uc1:menu id="Menu1" runat="server" enabled=true />
   ```

5. Proceed with designing the rest of your Web Forms page. You can switch to Design view to work with your page. The user control will be displayed using a glyph to indicate its location in the page, but will not display a WYSIWYG rendering in the designer. To edit the control, switch back to HTML view.

Working with User Controls Programmatically

The public properties, methods, and events of a user control that is registered in a page are exposed to the parent Web Forms page. By simply adding a declaration for the user control to the code-behind class for the Web Forms page, you can work with the complete object model of the user control to your page's code.

To set a property of a user control in a Web Forms page

1. Select the user control file in Solution Explorer and drag it onto your page. Note the ID of the user control displayed in the

page.

2. Press F7 to switch from Design view to the code-behind file.
3. In the Declarations area, add a line to declare the user control. For example, for a user control of type WebUserControl1 whose ID is myControl1:

```
' Visual Basic
Public Class MyPage
   Inherits System.Web.UI.Page
   Protected Menu1 As menu

// C#
public class MyPage : System.Web.UI.Page
{
   protected menu Menu1;
```

Note The ID in the code-behind declaration must exactly match the ID for the user control in Design view.

Now that you have a code declaration for the user control, all of the public properties, methods, and events of your user control are available, and will appear in the IntelliSense statement completion dropdowns.

4. Write code to call methods or set properties of your user control. For example:

```
' Visual Basic
Menu1.Visible = True
Menu1.DataBind()

// C#
Menu1.Visible = true;
Menu1.DataBind();
```

For more information, see Developing ASP.NET Server Controls and ASP.NET Server Control Event Model.

Adding User Controls to a Web Forms Page Programmatically

To add Web user controls to a Web Forms page, you must perform some steps that you do not normally need when adding existing Web Forms server controls. For details, see Creating Instances of User Controls Programmatically.

See Also

Introduction to Web User Controls | Creating Web User Controls | Introduction to Web Custom Controls | Recommendations for Web User Controls vs. Web Custom Controls | Adding Controls to a Web Forms Page Programmatically | Walkthrough: Creating a Web User Control

Introduction to Web Custom Controls

Web custom controls are compiled components that run on the server and that encapsulate user-interface and other related functionality into reusable packages. They can include all the design-time features of standard ASP.NET server controls, including full support for Visual Studio design features such as the Properties window, the visual designer, and the Toolbox.

> **Note** Web custom controls are not to be confused with Web user controls. For more information, see Recommendations for Web User Controls vs. Web Custom Controls.

There are several ways that you can create Web custom controls:

- You can compile a control that combines the functionality of two or more existing controls. For example, if you need a control that encapsulates a button and a text box, you can create it by compiling the existing controls together. For more information, see Developing a Composite Control.
- If an existing server control almost meets your requirements but lacks some required features, you can customize the control by deriving from it and overriding its properties, methods, and events. For more information, see Developing ASP.NET Server Controls and Web Server Controls Hierarchy.
- If none of the existing Web server controls (or their combinations) meet your requirements, you can create a custom control by deriving from one of the base control classes. These classes provide all the basic functionality of Web server controls, so you can focus on programming the features you need. For more information, see Developing Custom Controls: Key Concepts and Developing a Simple ASP.NET Server Control.

> **Security Note** At design time in Visual Studio, your code always runs fully trusted, even if the code will eventually be in a project where it would receive less-than-full trust at run time. This means that your custom control might work properly when you are testing it on your own computer, but might fail due to lack of adequate permissions in a deployed application. Be sure to test your controls in the security context in which they will run in real-world applications. For more information, see Code Access Security.

Introduction to Web User Controls | Recommendations for Web User Controls vs. Web Custom Controls

Recommendations for Web User Controls vs. Web Custom Controls

If none of the existing ASP.NET server controls meet the specific requirements of your applications, you can create either a Web user control or a Web custom control that encapsulates the functionality you need. The main difference between the two controls lies in ease of creation vs. ease of use at design time.

Web user controls are easy to make, but they can be less convenient to use in advanced scenarios. You develop Web user controls almost exactly the same way that you develop Web Forms pages. Like Web Forms, user controls can be created in the visual designer, they can be written with code separated from the HTML, and they can handle execution events. However, because Web user controls are compiled dynamically at run time they cannot be added to the Toolbox, and they are represented by a simple placeholder glyph when added to a page. This makes Web user controls harder to use if you are accustomed to full Visual Studio .NET design-time support, including the Properties window and Design view previews. Also, the only way to share the user control between applications is to put a separate copy in each application, which takes more maintenance if you make changes to the control.

Web custom controls are compiled code, which makes them easier to use but more difficult to create; Web custom controls must be authored in code. Once you have created the control, however, you can add it to the Toolbox and display it in a visual designer with full Properties window support and all the other design-time features of ASP.NET server controls. In addition, you can install a single copy of the Web custom control in the global assembly cache and share it between applications, which makes maintenance easier. For more information see global assembly cache.

If your control has a lot of static layout, a user control might make sense. If your control is mostly dynamically generated — for instance rows of a data-bound table, nodes of a tree view, or tabs of a tab control — a custom control would be a better choice.

The main differences between the two types are outlined in this table:

Web user controls	**Web custom controls**
Easier to create	Harder to create
Limited support for consumers who use a visual design tool	Full visual design tool support for consumers
A separate copy of the control is required in each application	Only a single copy of the control is required, in the global assembly cache
Cannot be added to the Toolbox in Visual Studio	Can be added to the Toolbox in Visual Studio
Good for static layout	Good for dynamic layout

Introduction to Web User Controls | Walkthrough: Creating a Web Custom Control | Walkthrough: Creating a Web User Control

Walkthrough: Creating a Web User Control

Web user controls are controls that you can define as you need them for your applications, using the same programming techniques that you use to write Web Forms pages. You can create Web user controls when you need to create reusable pieces of UI that will be used throughout your application. A user control can contain HTML, server controls, and event-handling logic. Like a compiled control, it can expose properties that the host Web Forms page can set.

> **Note** Web user controls are not to be confused with Web custom controls. For more information, see Recommendations for Web User Controls vs. Web Custom Controls.

The steps to create a user control are very similar to those for creating a Web Forms page. You design the UI visually by arranging ASP.NET server controls, HTML, and static text on the design surface, binding to data, and writing code to handle events raised by the controls. Like a Web Forms page, a user control can handle page processing events, such as **Page_Load**.

This walkthrough creates a menu selection control that passes the selected item back to the page in the URL query string. This style of navigation is useful when your application uses a single page to display a particular kind of data, but you also want to provide a filtered view of the data. For example, you might have a Sales page showing data that can be filtered by region. A user can navigate directly to the data he wishes to see by clicking a button that puts the filter in the URL as a query-string element, as in this example that limits the information displayed to sales in the northeast region:

```
http://sales/salesreport.aspx?region=northeast
```

In this walkthrough, you will create a control that displays information categories as a menu on a Web Forms page. It gets the categories and populates the menu dynamically from a data source on the page, in this case a string array. When a menu item is clicked, that menu item's index number in the array is added as a parameter to a URL. That URL is passed to the host page, which takes the parameter and displays the information that is associated with that index number in a Label control; in this case, the information is simply the category name from the same string array.

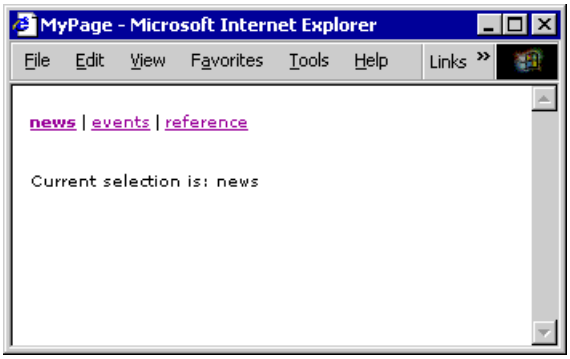
You will do the following steps to create the user control:

- Open a new user control in the designer
- Set a databinding expression for the user control
- Expose the data source and selection as properties to a Web Forms page
- Initialize the user control

You will also do the following to use the control on a Web Forms page:

- Add the user control to a page
- Create a data source for the user control
- Set the user control's properties
- Provide a filter presentation in the Web Forms page, based on the user control's selection
- Run the Web Forms page to test the control

When you finish, your page should look something like this:



Creating the User Control

The first step is to start a new project and add a Web user control to it.

To create the Web user control

1. On the **File** menu, point to **New**, and then click **Project**.

   The **New Project** dialog box appears.

2. In the **Project Types** pane, choose **Visual Basic Projects** or **Visual C# Projects**. In the **Templates** pane, select **ASP.NET Web Application** and click **OK**.

   A new project will be created with the default name at the default location.

3. Close the newly-created .aspx file. You won't need it in this walkthrough.
4. On the **Project** menu, click **Add Web User Control**.

   The **Add New Item** dialog box appears, with **Web User Control** selected.

5. Type **menu.ascx** in the **Name** box, and click **Open**. The user control opens in the designer.

To display the data in your user control, add a **DataList** control to the design surface. The **DataList** control takes each item from a data source, formats it and the entire data list according to the properties you specify, and displays the list of items. Because the list is dynamically generated based on the data source, this control is easily reusable.

To add the DataList control and set its properties

1. From the **Web Forms** tab of the Toolbox, add a **DataList** control to the menu.ascx page.

   This control will populate the menu by displaying a list of available options, which it will get from an array that is created in the host Web Forms page. To make the items appear on the page in the menu format "Item1 | Item2 | Item3", the **DataList** control display properties must be set correctly.

2. Make sure the **DataList** control is selected, and click **Property Builder** at the bottom of the Properties window to open the **DataList1 Properties** dialog box.
3. On the **General** page, in the **Repeat layout** group, set **Direction** to **Horizontal**.
4. On the **Format** page, in the **Objects** list, expand the **Items** node and select **Selected Items**. In the **Appearance** group, select **Bold**, and then click **OK**.

   This setting will make the menu item that is selected appear in bold letters.

5. Right-click the **DataList** control to show the shortcut menu, and then point to **Edit Template** and click **Separator Template**.
6. Position the insertion point in the blank row of the **Separator** template and type the "|" character.

   This character will be used to separate the menu items when they are listed.

Each data item that appears in the **DataList** menu will have an array index value, with a lower bound of 0. You will use this number to request the information associated with that menu item, by adding it as a parameter to the URL that is passed to the host page. To generate the URL, format the data items as hyperlinks using the **HyperLink** control, and bind that control to the data source. You can then design a binding expression that dynamically generates the appropriate request string for each hyperlink.

To add a HyperLink control and set the binding expression

1. Right-click the **DataList** control, and then point to **Edit Template** and click **Item Templates**. Several more template fields appear in the **DataList** control.

   The user needs to be able to click a menu item to retrieve the data related to that menu item. Therefore, each item needs to be a hyperlink.

2. From the **Web Forms** tab of the Toolbox, drag a **HyperLink** control to the blank row in the **DataList** control beneath the heading **ItemTemplate**.
3. Make sure that the **HyperLink** control is selected, and then select **(DataBindings)** in the Properties window and click the ellipsis button in the value field.

   The **DataBindings** dialog box appears. The **Text** property is selected by default in the **Bindable Properties** list.

4. In the **Binding for Text** group, under **Simple binding**, expand the **Container** node and select **DataItem**.

   This will bind the **Text** property of each hyperlink to the data item of the container, which in this case is the **DataList** control. The **DataList** control will receive its data items from the array that is created in the host Web Forms page.

5. In the **Bindable Properties** list, select the **NavigateUrl** property.

Note When you click the **NavigateUrl** property, the icon next to the **Text** property changes to show that it is data-bound.

6. In the **Binding for NavigateUrl** group, under **Simple binding**, select **ItemIndex**.

   This is the index number of the data item in the array. To append this number correctly to the URL so that the URL retrieves the data item at that index number, you must format it as a parameter. Name the parameter "category".

   Security Note The URL associated with a hyperlink can be tampered with by a malicious user. For more information, see Scripting Exploits.

7. In the **Format** box, enter this string (note the curly braces around the 0):

   ```
   ?category={0}
   ```

   Now you must complete the URL so that it points to the host Web Forms page.

8. Click **Custom binding expression** and add this code to the beginning of your almost-complete databinding expression:

   ```
   Request.Path +
   ```

   Your complete custom databinding expression should be:

   ```
   Request.Path + DataBinder.Eval(Container, "ItemIndex", "?category={0}")
   ```

9. Click **OK** to close the DataBindings dialog box.

The databinding expression that you entered contains the syntax for building a URL at run time, based on information from the link associated with the array number.

When the user control runs, this expression is evaluated as follows:

- First, **Request.Path** is replaced by the name of the current page. This approach lets you use your menu control on any page, regardless of what it is named. For more information, see HttpRequest.Path Property.
- Next, the **DataBinder.Eval** method takes the item's index number, and substitutes it for the "{0}" token in the format string. For more information, see DataBinder.Eval Method.

For example, if the hosting page is called MyPage.aspx, and the index for this item is 1, the generated URL would be:

```
MyPage.aspx?category=1
```

Exposing Properties to the Web Forms Page

You can bind a **DataList** control to a number of different types of data sources. For the sake of simplicity, this walkthrough binds the **DataList** control to a simple string array, which is passed from the Web Forms page to the user control via a property exposed by the user control.

To declare the array and selection properties

1. Press **F7** to switch from Design view to the code-behind file.
2. Add a public, class-level declaration for a string array, and name it `values`.

   This array will hold the list of data items.

3. Similarly, declare `selection` as **Integer** and initialize it to -1.

   This variable will hold the index value for the menu item that the user selects. Since -1 is not an index value in the array, the variable will not be assigned an index value on initialization.

   The top section of your code should look something like this:

   ```
   ' Visual Basic
   Public MustInherit Class menu
   ```

```
   Inherits System.Web.UI.UserControl
   Protected WithEvents DataList1 As System.Web.UI.WebControls.DataList
   Public values() As String
   Public selection As Integer = -1

// C#
public abstract class menu : System.Web.UI.UserControl
{
   protected System.Web.UI.WebControls.DataList DataList1;
   public string[] values;
   public int selection = -1;
```

Initializing the Control

Now that the pathways and formats are established, you need to add the code to initialize the connection between the control and the data. Use the page load event to do this initialization.

1. In the **Page_Load** procedure, set `values` to be the **DataSource** property for the **DataList** control.
2. Set **selection** to be the **SelectedIndex** property for the **DataList** control.
3. Call the **DataBind()** method of the **DataList** control to create the DataList items.

   Your **Page_Load** procedure will look like this:

```
' Visual Basic
Private Sub Page_Load(ByVal sender As System.Object, _
      ByVal e As System.EventArgs) Handles MyBase.Load
   DataList1.DataSource = values
   DataList1.SelectedIndex = selection
   DataList1.DataBind()
End Sub

// C#
private void Page_Load(object sender, System.EventArgs e)
{
   DataList1.DataSource = values;
   DataList1.SelectedIndex = selection;
   DataList1.DataBind();
}
```

4. Save and close the control.

Consuming the User Control

Now that you have created a user control, you will actually use it in a Web Forms page. It is possible to use your control on multiple pages and bind it to different data on each page. In this walkthrough, however, you consume the user control on a single page called MyPage.aspx.

To add the user control to a Web Forms page

1. On the **Project** menu, click **Add Web Form**.

   The **Add New Item** dialog box appears with **Web Form** selected.

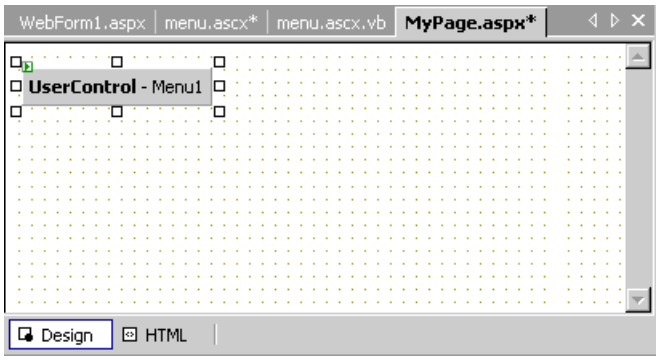
2. Change the **Name** to **MyPage.aspx**, and click **Open**.

   The new Web Forms page opens in Design view.

3. Select the menu.ascx file in Solution Explorer and drag it onto your page. It will appear as a user control, with the ID `Menu1`.

   The user control will be displayed on the page as a tag showing its type and name; there is no graphical display for user controls within a page since this type of control is not fully compiled until you run the page.

   User Control Glyph on a Web Forms Page



4. From the **Web Forms** tab of the Toolbox, add a **Label** control to the page.

   This control is used to display the information associated with the selected menu item.

5. Save your files.

Since Visual Studio does not automatically add a declaration of user controls to the code, the next step is to add the declaration manually.

To add a code-behind declaration for the user control

1. Press **F7** to switch from Design view to the code-behind file.
2. In the Declarations area, add a line to declare the user control **Menu1** as menu.

```
' Visual Basic
Public Class MyPage
   Inherits System.Web.UI.Page
   Protected WithEvents Label1 As System.Web.UI.WebControls.Label
   Protected Menu1 As menu

// C#
public class MyPage : System.Web.UI.Page
{
   protected System.Web.UI.WebControls.Label Label1;
   protected menu Menu1;
```

Now that you have a code declaration for the user control, you must set its properties programmatically.

To create a data source for the user control

1. In the **Page_Load** method of the Web Forms page, declare a string array and name it **values**. This is the array that will be called by the user control that you created. Populate the array with three items: "News", "Events", and "Reference".
2. Assign the array to the `values` property of the `Menu1` user control.

   Your code should look like this:

```
' Visual Basic
' set datasource for menu
Dim values() As String = New String() {"News", "Events", "Reference"}
Menu1.values = values

// C#
//set datasource for menu
String[] values = new String[]{"News", "Events", "Reference"};
Menu1.values = values;
```

To find out which item in the menu is selected, check the "category" parameter that you set when you created the custom binding expression for the **Hyperlink** control.

To capture the user control selection

1. In the **Page_Load** method, add a line of code to copy the current selection (if any) from the URL query string:

```
' Visual Basic
Dim selectionId As String = Request.Params("category")

// C#
String selectionId = Request.Params["category"];
```

Security Note Information passed in a query string can be tampered with by a malicious user. Do not rely on query strings to convey important or sensitive data. For more information, see Scripting Exploits.

2. If the selection was set, pass it on to the user control via the control's `selection` property and set the text of the **Label** control to indicate the current selection. The Web Forms page can use the selection information to filter the view it displays.

```
' Visual Basic
If (selectionId <> "") Then
   Dim SelectIndex As Integer = CInt(selectionId)
   Menu1.selection = SelectIndex
   Label1.Text = "Current selection is: " & values(SelectIndex)
End If

// C#
if(selectionId != "")
   {
      int SelectIndex = Convert.ToInt16(selectionId);
      Menu1.selection = SelectIndex;
      Label1.Text = "Current selection is: " + values[SelectIndex];
   }
```

That completes the Web Forms page. Your entire **Page_Load** procedure should look like this:

```
' Visual Basic
Dim values() As String = New String() {"news", "events", "reference"}
Menu1.values = values
Dim selectionId As String = Request.Params("category")
If (selectionId <> "") Then
   Dim SelectIndex As Integer = CInt(selectionId)
   Menu1.selection = SelectIndex
   Label1.Text = "Current selection is: " & values(SelectIndex)
End If

// C#
String[] values = new String[]{"News", "Events", "Reference"};
Menu1.values = values;
String selectionId = Request.Params["category"];
if(selectionId != "")
   {
      int SelectIndex = Convert.ToInt16(selectionId);
      Menu1.selection = SelectIndex;
      Label1.Text = "Current selection is: " + values[SelectIndex];
   }
```

3. Save and close the page.

Testing the Web Forms Page

You can now test your page to see the functionality of the menu.

To test the Web Forms page

1. Right-click MyPage.aspx in Solution Explorer and choose **Set As Start Page** on the shortcut menu.

2. Press F5 to run MyPage.aspx and test the user control. Click each of the menu selections to test their functionality.

The user control displays each string that is passed from the array in the Web Forms page as a separate link. You set the **DataSource** property of the **DataList** control to the array and use the **DataList** to render a hyperlink for each of the items in the **DataSource** property. The **DataList** control also takes care of applying a different visual style to the selected link.

Walkthrough: Converting a Web Forms Page to a User Control | Overview of Web Application Security Threats

Walkthrough: Converting a Web Forms Page to a User Control

If you have developed a Web Forms page and decide you would like to access its functionality throughout your application, you can make some minor alterations to the file to change it to a user control. Web user controls are very similar to Web Forms pages, and they are created using the same techniques. When you convert a Web Forms page to a Web user control, you create a reusable UI component that you can use on other Web Forms pages.

For this walkthrough, you will create a basic Web Forms page that presents a personalized welcome message to the user. To convert the page to a Web user control, you will make a few changes to the code:

- Change the code-behind base class from **Page** to **UserControl**
- Delete the `<html>`, `<head>`, `<body>`, and `<form>` tags from the .aspx file
- Change the ASP.NET directive type from **@ Page** to **@ Control**
- Change the **Codebehind** attribute to refer to the control's code-behind class file (ascx.vb or ascx cs)
- Change the .aspx file extension to .ascx

To test the control, you will create a new Web Forms page, add the control to it, and open the page in a browser.

Creating the Web Forms Page

The first step is to create a Web application and a Web Forms page.

To create the project and form

1. On the **File** menu, point to **New**, then click **Project**.
2. In the **New Project** dialog box, do the following:
   a. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**.
   b. In the **Templates** pane, choose **ASP.NET Web Application**.
   c. In the **Location** box, enter the complete URL for your application, including http://, and the name of the server. The last part of the URL is the name of your project; for this walkthrough, name your project **Conversion**. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

      Tip If you already have a solution open, choose **Close Solution** so that your new Web Forms project will be part of its own solution.

   When you click **OK**, a new Web Forms project is created at the root of the Web server you specified. In addition, a new Web Forms page called WebForm1.aspx is displayed in the Web Forms Designer in Design view.

You can now add a few controls and write some code to display a personalized welcome message.

To add controls and program them

1. From the **Web Forms** tab of the Toolbox, drag a **TextBox** control onto the designer.
2. Drag a **Label** control to the left of the text box. In the **Properties** window, change the **Label** control's **Text** property to **Enter Name:**.
3. Drag a **Button** control underneath the text box, and change the **Text** property to **Enter**.
4. Drag a second **Label** control underneath the button, and delete the default text so that the **Text** property is empty.
5. Double-click the **Button** control to open the **Code** view with a **Button_Click** event handler added.
6. Add the following code to the **Button1_Click** procedure:

```
' Visual Basic
Label2.Text = "Hi " & TextBox1.Text & ", welcome to ASP.NET!"

// C#
Label2.Text = "Hi " + TextBox1.Text + ", welcome to ASP.NET!";
```

   Do not close this file, because you will return to it later in the walkthrough.

   Security Note User input in a Web Forms page can include potentially malicious client script. By default, the

Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

7. Press CTRL+F5 to run the Web Forms page and test it. When you are finished, close the browser that opened when you tested the page.

Now you have a basic Web Forms page that you can convert to a Web user control.

Converting the Page to a User Control

Since the `<html>`, `<body>`, and `<form>` elements are not included in user controls, you must remove these elements and include them in the parent Web Forms page instead. You must also change the ASP.NET directive type in the Web Forms page from @ Page to @ Control. These ASP.NET directives specify settings used by the page and user control compilers. For more information, see Directive Syntax.

To convert the Web Forms page to a user control

1. Return to WebForm1.aspx in the designer, and switch to HTML view by clicking the HTML tab at the bottom of the designer window.
2. Delete the `<html>` tags, `<!doctype>` tag, `<head>` tags and inner content, `<body>`, and `<form>` tags from the .aspx file. If you are using Visual Basic, the HTML looks like this:

```
<%@ Page Language="vb" AutoEventWireup="false"
      Codebehind="WebForm1.aspx.vb" Inherits="Conversion.WebForm1">
<asp:TextBox id="TextBox1" runat="server"></asp:TextBox>
<asp:Label id="Label1" runat="server">Enter Name:</asp:Label>
<asp:Button id="Button1" runat="server" Text="Enter"></asp:Button>
<asp:Label id="Label2" runat="server"></asp:Label>
```

If you are using C#, the HTML will look identical except for the first line, which will look like this:

```
<%@ Page Language="cs" AutoEventWireup="false"
      Codebehind="WebForm1.aspx.cs" Inherits="Conversion.WebForm1">
```

Note The Code Editor adds underlines that normally indicate problems with the code. These marks will disappear after the conversion is completed.

3. Change the ASP.NET directive type from @ **Page** to @ **Control**. In a Visual Basic project, it will look like this:

```
<%@ Control Language="vb" AutoEventWireup="false"
      Codebehind="WebForm1.aspx.vb" Inherits="Conversion.WebForm1">
```

In a C# project, it will look like this:

```
<%@ Control Language="cs" AutoEventWireup="false"
      Codebehind="WebForm1.aspx.cs" Inherits="Conversion.WebForm1">
```

4. Change the **Codebehind** attribute reference of the directive to reflect the fact that the .aspx extension will be changed to .ascx, which is the extension for user controls. You will also change the name of the control to welcome.ascx later in this walkthrough, so set the **Codebehind** attribute to **welcome.ascx.vb** or **welcome.ascx.cs** as appropriate.
5. Similarly, change the **Inherits** attribute of the directive to refer to **Conversion.welcome**.
6. Return to the **WebForm1.aspx.vb** or **WebForm1.aspx.cs** file.
7. Change the base class from **System.Web.UI.Page** to **System.Web.UI.UserControl**, and change the **Public Class** declaration from **WebForm1** to **welcome**.

```
' Visual Basic
Public Class welcome
   Inherits System.Web.UI.UserControl

// C#
```

```
public class welcome : System.Web.UI.UserControl
```

8. Save and close the code-behind file and the .aspx file.
9. Right-click **WebForm1.aspx** in Solution Explorer and click **Rename** on the shortcut menu.
10. Change the name of the file to **welcome.ascx** to reflect its new function. It is important to note that you must change the file name extension from .aspx to .ascx. When the confirmation dialog appears, click **OK**.

The file is now a Web user control, and it is ready to be consumed by Web Forms pages throughout your project.

Testing the User Control

You can test your user control by creating a new Web Forms page and adding the control to it.

To test the user control

1. On the **Project** menu, click **Add Web Form**. The **Add New Item** dialog appears with **Web Form** selected.
2. Change the **Name** to WelcomeTest.aspx and click **Open**. The new Web Forms page opens in the designer.
3. Drag welcome.ascx from Solution Explorer onto the design surface.
4. Right-click WelcomeTest.aspx in Solution Explorer and click **Set As Start Page** on the shortcut menu.
5. Press F5 to run the Web Forms page and test it.

Introduction to Web User Controls | Recommendations for Web User Controls vs. Web Custom Controls | Developing User Controls in a Code-Behind File | Overview of Web Application Security Threats

Walkthrough: Creating a Web Custom Control

If none of the existing ASP.NET server controls meet the requirements of your application, you can create a custom control by deriving from one of the base control classes. These classes provide all the basic functionality of server controls, so you can focus on programming the features you need.

In this walkthrough, you will use the code for a custom Label control that is included by default in the **Web Control Library** template. This control is derived from the WebControl class and behaves the same as a standard Label control with the added property of rendering the value of the Text property as a hyperlink. To complete the walkthrough, you will perform these procedures:

- Create two projects in the same solution — one for the custom Label control, and one for a Web Forms page to consume and test the control.
- Add the control to the Toolbox.
- Consume the custom control by adding it to the Web Forms page.
- Create a custom designer for the control.
- Test the control in the browser.

> **Note** The **Web Control Library** template is not available in the Standard Edition of Visual Basic and Visual C# .NET. For more information, see Visual Basic Standard Edition Features or Visual C# Standard Edition Features.

The emphasis in this walkthrough is not on writing code for the control, but rather on what to do to make a control once the code is written.

Creating the Projects

The first step is to start a new project with the custom control template and build the control.

To create the custom control

1. On the **File** menu, point to **New**, and then click **Project**.

   The **New Project** dialog box appears.

2. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**. Select **Web Control Library** in the **Templates** pane.
3. Change the **Name** to **CustomLabel** and click **OK**.

   The new project is created, and **WebCustomControl1** opens in the Code Editor.

   Code for a custom **Label** control is included in the **Web Control Library** template by default. This is the control you will use in this walkthrough.

4. On the **Build** menu, click **Build CustomLabel** to compile the control.

   The control is compiled as CustomLabel.dll. By default, it is created in the **Bin** folder inside the **CustomLabel** project folder.

5. Save the file.

Now that the control has been created, you will add a Web Forms page to the same solution so that the page is convenient for testing the control.

To create the Web Forms page

1. On the **File** menu, point to **Add Project**, and then click **New Project**.

   The **Add New Project** dialog box appears.

2. In the **Project Types** pane, choose either **Visual Basic Projects** or **Visual C# Projects**. Select **ASP.NET Web Application** in the **Templates** pane.
3. In the **Location** box, enter the complete URL for your application, including http://, and the name of the server. The last part of the URL is the name of your project; for this walkthrough, name your project **LabelWebForm**. The Web server must have IIS version 5 or later and the .NET Framework installed on it. If you have IIS on your computer, you can specify `http://localhost` for the server. (If you normally use a proxy server to access the Internet, you might need to configure Internet Explorer to bypass the proxy server in order to use localhost.)

4. Click **OK**.

   The new project is created, and **WebForm1** opens in the designer.

5. Save the project.

Adding the Control to the Toolbox

Now that your control has been compiled and you have a Web Forms page ready to test it, you can add the control to the Toolbox so it will be readily available for use.

To add your control to the Toolbox

1. On the **Tools** menu, click **Add/Remove Toolbox Items**.
2. On the **.NET Framework Components** tab of the **Customize ToolBox** dialog box, click the **Browse** button. Find **CustomLabel.dll**, select it, and click **Open** to add **WebCustomControl1** to the list of components in the **Customize Toolbox** dialog box.
3. Select **WebCustomControl1** in the list of .NET Framework components and click **OK**. **WebCustomControl1** is added to the Toolbox.

When you are finished, you should see an icon on the toolbar that looks like this:

The next step is to test the control in the page.

To add the control to the Web Forms page and test it

1. Open **WebForm1** in Design view and drag **WebCustomControl1** from the Toolbox to the page.

   The control's default rendering, which is simply the name of the control followed by its ID, appears in the Design view.

2. Switch to HTML view, and verify that an **@ Register** directive for the control's assembly is added to the page's HTML, with TagPrefix "cc1".
3. Set the **Text** property of the control to **Hello**.

   The control's appearance in Design view is updated to show the new text.

Next, you are going to customize the control, so you need to remove it from the Toolbox.

To remove the control from the Toolbox

1. Right-click **WebCustomControl1** in the Toolbox and click **Delete** on the shortcut menu. This action will not delete the control from the project, only from the Toolbox.
2. Close the Web Forms page without saving.

The custom Label control is now functional, but it's not very attractive and the tag is not distinctive in the code. The next step is to individualize the control.

Individualizing the Control

The control is using the default icon in the Toolbox and the default tag prefix "cc1". To make the control more easily identifiable, change the tag prefix and create a new icon.

To change the tag prefix

1. Under the **CustomLabel** project in Solution Explorer, double-click **AssemblyInfo** to open the AssemblyInfo file in the designer. Add an **Imports** statement (in Visual Basic) or **using** statement (in Visual C#) at the top of the AssemblyInfo page:

```
' Visual Basic
Imports System.Web.UI

// C#
using System.Web.UI;
```

2. Add an **Assembly: TagPrefix** attribute to the list of assembly attributes. This will specify the new **TagPrefix** for the **CustomLabel** control, in this case **xxx**.

```
' Visual Basic
<Assembly: TagPrefix("CustomLabel", "xxx")>

//C#
[assembly: TagPrefix("CustomLabel", "xxx")]
```

To create a new icon

1. Select the **CustomLabel** project in Solution Explorer. On the **Project** menu, click **Add New Item**.

   The **Add New Item** dialog box appears.

2. Select **Bitmap File** in the Templates pane, change the **Name** to **WebCustomControl1.bmp**, and click **Open**. The new bitmap file appears in Solution Explorer and opens in the designer.

   > **Note** For this walkthrough, the name of the icon file name must match that of the control class exactly (WebCustomControl1), including capitalization.

3. In the Properties window, change both the **Height** and **Width** properties of the bitmap to 16. Icons must be 16 by 16 pixels in size.
4. Draw a distinctive design on the bitmap, using several colors, so you can recognize the icon.
5. Save and close the bitmap file.
6. Select **WebCustomControl1.bmp** in Solution Explorer. In the Properties window, change the **Build Action** property to **Embedded Resource**.
7. Select the **CustomLabel** project in Solution Explorer. On the **Build** menu, click **Rebuild CustomLabel**.
8. Save all your work.

When you add the control to the Toolbox now, the icon you created will show up next to the control name. When you consume the control on your Web Forms page, the control's HTML tag will contain the identifying prefix that you specified.

To consume the custom control

1. Add **WebCustomControl1** to the Toolbox again.

   The control appears with the icon you created. Depending on your settings, it may appear under the **General** tab of the Toolbox.

2. Reopen the Web Forms page named **WebForm1** and drag the control onto it.

   > **Note** The **Text** property has reverted to the default, because you closed the Web Forms page without saving earlier.

3. Switch to HTML view and verify that the **TagPrefix** attribute of the **@ Register** directive is **xxx**.
4. Because you are going to make another modification to the control, delete **WebCustomControl1** from the Web Forms page, but leave it in the Toolbox.

Your custom control is now fully functional and individualized, but its appearance on the design surface is not very helpful. To make the control look better, you will add a custom designer to it.

Creating a Custom Designer

Designers are classes that allow you to modify the design-time appearance and behavior of components and controls. Although the usual goal of any WYSIWYG form designer is to minimize differences between design-time and run-time appearance, at times special design-time cues are necessary. For more information, see Custom Designers.

In this walkthrough, you will implement a custom designer that causes the custom control to render its text as a hyperlink.

To create a custom designer for the control

1. Select the **CustomLabel** project in Solution Explorer.
2. On the **Project** menu, click **Add Reference** and add a reference to **System.Design.dll**.
3. On the **Project** menu, click **Add New Item**.

   The **Add New Item** dialog box appears.

4. Select **Class** in the Templates pane, change the **Name** to **SampleDesigner**, and click **Open**. The new class file appears in Solution Explorer and opens in the designer.
5. Add code that overrides the base class's GetDesignTimeHtml method. This method is called at design time to get the representation of your control. In the overridden method, do the following:
   a. Get the **Text** property of the custom control.
   b. If the **Text** property has been set (that is, it's not an empty string), create a new **Hyperlink** control, set its properties to match the original control, and call the **Hyperlink** control's **Render** method.

The end result is that the **Hyperlink** control is displayed in the designer using the value of the **Text** property.

The code to perform these steps looks like the following, which is a complete listing of the **SampleDesigner** file:

```
' Visual Basic
Imports System
Imports System.IO
Imports System.Web
Imports System.Web.UI
Imports System.Web.UI.WebControls
Imports System.Web.UI.Design

Public Class SampleDesigner
    Inherits System.Web.UI.Design.ControlDesigner

    Public Overrides Function GetDesignTimeHtml() As String
        ' Component is the control instance, defined in the base
        ' designer
        Dim ctl As WebCustomControl1 = CType(Me.Component, _
            WebCustomControl1)
        If (ctl.Text <> "") Then
            Dim sw As New StringWriter()
            Dim tw As New HtmlTextWriter(sw)
            Dim placeholderlink As New HyperLink()

            ' put control text into the link's Text
            placeholderlink.Text = ctl.Text
            placeholderlink.NavigateUrl = ctl.Text
            placeholderlink.RenderControl(tw)

            Return sw.ToString()
        Else
            Return Me.GetEmptyDesignTimeHtml()
        End If
    End Function
End Class

// C#

using System;
using System.IO;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;
using System.Web.UI.Design;

namespace CustomLabel
{
   public class SampleDesigner : System.Web.UI.Design.ControlDesigner
   {
```

```
        public override string GetDesignTimeHtml()
        {
        // Component is the control instance, defined in the base
        // designer
        WebCustomControl1 ctl = (WebCustomControl1 ) Component;

        if (ctl.Text != "" && ctl.Text != null)
        {
           StringWriter sw = new StringWriter();
           HtmlTextWriter tw = new HtmlTextWriter(sw);

           HyperLink placeholderLink = new HyperLink();

           // put control text into the link's Text
           placeholderLink.Text = ctl.Text;
           placeholderLink.NavigateUrl = ctl.Text;
           placeholderLink.RenderControl(tw);

           return sw.ToString();
        }
        else
           return GetEmptyDesignTimeHtml();
        }
     }
  }
```

6. Open **WebCustomControl1.vb** or **WebCustomControl1.cs** (depending on the language you are using) in the designer, and add this attribute to the attribute list just before the WebCustomControl1 class declaration:

```
Designer("CustomLabel.SampleDesigner, CustomLabel")
```

The WebCustomControl1 class declaration should look like this:

```
' Visual Basic
<Designer("CustomLabel.SampleDesigner, CustomLabel"), _
DefaultProperty("Text"), ToolboxData("<{0}:WebCustomControl1 _
runat=server></{0}:WebCustomControl1>")> Public Class WebCustomControl1

// C#
[Designer("CustomLabel.SampleDesigner, CustomLabel"), DefaultProperty("Text"), ToolboxDat
a("<{0}:WebCustomControl1 runat=server></{0}:WebCustomControl1>")]
public class WebCustomControl1 : System.Web.UI.WebControls.WebControl
```

7. On the **Build** menu, click **Build Solution** so that both projects are built.
8. Save all, and close all the open files.

Testing the Control

To test that the Text property works correctly

1. Open **WebForm1** in the designer.
2. Drag **WebCustomControl1** from the Toolbox onto the page.
3. Set the **Text** property of your Web custom control to **Hello**. The text should appear as a hyperlink on the Web Forms page.
4. Save WebForm1.

To test the control in a browser

1. Select **WebForm1** in Solution Explorer. On the **File** menu, click **View in Browser**.
2. Verify that **Hello** shows up in the browser. The text looks like a label, not like a hyperlink.

Note At design time in Visual Studio, your code always runs fully trusted, even if the code will eventually be in a project where it would receive less than full trust at run time. This means that your custom control might work properly when you are testing it on your own computer, but might fail due to lack of adequate permissions in a deployed application. Be sure to test your controls in the security context in which they will run in real-world applications.

Introduction to Programming XML Web Services in Managed Code

XML Web services make possible the exchange of data in the form of XML messages between heterogeneous systems. Although remote access of data and application logic is not a new concept, doing so in a loosely coupled fashion is. Previous attempts, such as DCOM, IIOP, and Java/RMI, required tight integration between the client and the server and used platform and implementation specific binary data formats. While such protocols require a particular component technology or object-calling convention, XML Web services do not. The only assumption made between the client and the server is that recipients will understand the messages they receive. In other words, the client and server agree to a contract, in this case described using WSDL and XSD, and then communicate by generating messages that honor the contract over a specified transport like HTTP. As a result, programs written in any language, using any component model, and running on any operating system can access XML Web services. Furthermore, the flexibility of using a text format like XML makes possible the message exchange to evolve over time in a loosely coupled way. This loose coupling is mandatory in environments where the simultaneous updating of all parties in the message exchange is not possible.

You create XML Web services using the ASP.NET page framework, enabling these XML Web services to access the many features of the .NET Framework, such as authentication, caching, and state management. Because ASP.NET and the .NET Framework are the basis for XML Web services in managed code, developers can focus on creating or accessing XML Web services without needing to write infrastructure code.

In the ASP.NET application model, Web pages intended for the browser use the .aspx extension. To differentiate XML Web services from regular ASP.NET pages, XML Web services use the .asmx extension.

There are two fundamental roles when working with XML Web services:

- **Creating an XML Web service** — When you create an XML Web service, you are creating an application that exposes functionality to XML Web service clients.
- **Accessing an XML Web service** — When you access an XML Web service, your client application locates, references, and uses the functionality contained within a separate XML Web service. The client of an XML Web service is typically an application that is able to send, receive, and process messages to and from the XML Web service. However, the minimum requirement is that the client must be able to send messages to the XML Web service. This includes all applications using the .NET Framework.

XML Web services can be either stand-alone applications or sub-components of a larger Web application. For example, suppose you are creating a Web application that sells books online. Your Web application might interact with XML Web services as follows:

- **Creating an XML Web service** — Your application exposes its order processing logic as an XML Web service, which your affiliate Web sites can in turn use in their Web applications to sell books through your online store without requiring their customers to visit your site.
- **Accessing an XML Web service** — Your application accesses an XML Web service provided by another online company that specializes in writing and supplying book reviews for online booksellers. When a visitor to your online store views the details of a particular book, they also see the reviews of that book on the same page.

Remember, XML Web services are accessible from just about any other kind of application, including other XML Web services, Web applications, Windows applications, and console applications. The minimum requirement is that the client must be able to send messages to the XML Web service.

Walkthrough: Calling XML Web Services from Windows Forms

A new aspect of Visual Studio is XML Web services, which provides the ability to exchange messages in a loosely coupled environment using standard protocols such as HTTP, XML, XSD, SOAP, and WSDL. The messages can be structured and typed or loosely defined. Because Web services are based on standard protocols, your Web service applications can communicate with a broad variety of implementations, platforms, and devices. For more information, see XML Web Services in Managed Code.

Web services can be used to enhance the functionality of Windows Forms. Connecting Windows Forms to Web services is as simple as making calls to Web service methods, which are processed on a server that then returns the results of the method call.

There are two types of Web service methods, synchronous and asynchronous. When synchronous Web service methods are called, the caller waits for the Web service to respond before continuing operations. When asynchronous Web service methods are called, you can continue to use the calling thread while waiting for the Web service to respond. This allows you to use the existing set of threads efficiently in the client application. For more information about working with synchronous and asynchronous Web service methods, see Accessing XML Web Services in Managed Code.

Synchronous Web Service Methods

A call to a synchronous Web service method involves calling the method and waiting for the computation to occur on the server and return a value before continuing with the rest of the code in the Windows Form.

To create an XML Web service

1. Create a Web service application. For more information, see Creating XML Web Services in Managed Code.
2. In Solution Explorer, right-click the .asmx file and choose **View Code**.
3. Create a Web service method that does addition. This following Web service method will take two integers and add them, returning the sum:

```
' Visual Basic
<WebMethod()> Public Function WebAdd(ByVal x As Integer, ByVal y As Integer) As Integer
   Return x + y
End Function

// C#
[WebMethod]
public int WebAdd(int x, int y)
{
   return x + y;
}
```

4. Create another Web service method that does multiplication. The following Web service method will take two integers and multiply them, returning the product:

```
' Visual Basic
<WebMethod()> Public Function WebMultiply(ByVal x As Integer, ByVal y As Integer) As Inte
ger
   Return x * y
End Function

// C#
[WebMethod]
public int WebMultiply(int x, int y)
{
   return x * y;
}
```

5. From the **Build** menu, choose **Build Solution**. You can also browse to the .asmx file you created in this project to learn more about Web services. Your Web service is now available for calling from a Windows Form.

To call an XML Web service synchronously

1. Create a new Windows application. For more information, see Creating a Windows Application Project.

   Security Note Calls to Web Methods require a privilege level granted by the System.Net.WebPermisson class. If you are running in a partial-trust context, the process might throw an exception. For more information, see Code Access Security Basics.

2. Add a reference to the Web service created above. For details, see Adding and Removing Web References.
3. From the Toolbox, add three **TextBox** controls and two **Button** controls. The text boxes will be for the numbers, and the buttons will be used for the calculations and to call the Web service methods.
4. Set the properties of the controls as follows:

Control	Property	Text
TextBox1	Text	0
TextBox2	Text	0
TextBox3	Text	0
Button1	Text	Add
Button2	Text	Multiply

5. Right-click the form and choose **View Code**.
6. Create an instance of the Web service as a member of the class. You need to know the name of the server where you created the Web service above.

```
' Visual Basic
' Replace localhost below with the name of the server where
' you created the Web service.
Dim MathServiceClass As New localhost.Service1()

// C#
localhost.Service1 MathServiceClass = new localhost.Service1();
```

7. Create an event handler for Button1's **Click** event. For details, see Creating Event Handlers on the Windows Forms Designer.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button1.Click
' Create instances of the operands and result.
   Dim x, y, z As Integer
' Parse the contents of the text boxes into integers.
   x = Integer.Parse(TextBox1.Text)
   y = Integer.Parse(TextBox2.Text)
' Call the WebAdd Web service method from the instance of the Web service.
   z = MathServiceClass.WebAdd(x, y)
   TextBox3.Text = z.ToString
End Sub

// C#
private void button1_Click(object sender, System.EventArgs e)
{
// Create instances of the operands and result.
   int x, y, z;
// Parse the contents of the text boxes into integers.
   x = int.Parse(textBox1.Text);
   y = int.Parse(textBox2.Text);
// Call the WebAdd Web service method from the instance of the Web service.
   z = MathServiceClass.WebAdd(x, y);
   textBox3.Text = z.ToString();
}
```

Visual C# Note Be sure that the necessary code to enable the event handler is present. In this case, it would be similar to the following:

this.button1.Click += new System.EventHandler(this.button1_Click);

8. Create an event handler for Button2's **Click** event in the same fashion, and add the following code.

```
' Visual Basic
Private Sub Button2_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Han
dles Button2.Click
' Create instances of the operands and result.
   Dim x, y, z As Integer
' Parse the contents of the text boxes into integers.
   x = Integer.Parse(TextBox1.Text)
   y = Integer.Parse(TextBox2.Text)
' Call the WebMultiply Web service method from the instance of the Web service.
   z = MathServiceClass.WebMultiply(x, y)
   TextBox3.Text = z.ToString
End Sub

// C#
private void button2_Click(object sender, System.EventArgs e)
{
// Create instances of the operands and result.
   int x, y, z;
// Parse the contents of the text boxes into integers.
   x = int.Parse(textBox1.Text);
   y = int.Parse(textBox2.Text);
// Call the WebAdd Web service method from the instance of the Web service.
   z = MathServiceClass.WebMultiply(x, y);
   textBox3.Text = z.ToString();
}
```

Visual C# Note Be sure that the necessary code to enable the event handler is present. In this case, it would be similar to the following:

this.button2.Click += new System.EventHandler(this.button2_Click);

9. Press F5 to run your application. Enter values into the first two text boxes. When you press the **Add** button, the third text box should show their sum. When you press the **Multiply** button, the third text box should show their product.

Note The first call to a Web service takes a while for the server to process, because the Web service is instantiated on the server. Keep this in mind when pressing the buttons in your application. This lag is dealt with in the section below.

Asynchronous Web Services

When you call asynchronous Web service methods, the application continues to run while waiting for the Web service to respond. This allows you to use the resources efficiently in the client application. This is a far more resource-savvy way to implement Web services within your Windows application.

For details, see Accessing an XML Web Service Asynchronously in Managed Code.

Creating XML Web Services in Managed Code

You create XML Web services in managed code using the ASP.NET page framework. You start by creating an .asmx file. This file contains the **WebService** directive, which identifies the public class that implements the XML Web service logic. The XML Web service class contains one or more public methods for exposure in an XML Web service. These XML Web service methods are prefaced with the **WebMethod** attribute. ASP.NET handles the infrastructure to expose those methods as an XML Web service. For more information, see Code Model for XML Web Services in Managed Code.

To create XML Web services in managed code using Visual Studio, you need access to a Web server configured for developing ASP.NET applications. You develop XML Web services in managed code on a *development server*. By default, the development server is the machine on which you installed Visual Studio. Typically, you develop and build the project on a development server, and then deploy it to another server (the *deployment server*) that will host the XML Web service. However, if development occurs directly on the server that will host the XML Web service, the development server and deployment server are the same. For more information, see Creating Web Projects and Visual Studio .NET Software Requirements.

XML Web Services Created with ATL Server

Describes how to create, distribute, and consume XML Web services using ATL Server and C++.

Code Model for XML Web Services in Managed Code

XML Web services consist of two parts: the XML Web service entry point and the code that implements the XML Web service functionality. In ASP.NET, the .asmx file is a text file that serves as the addressable entry point for the XML Web service. It references code in pre-compiled assemblies, a code-behind file, or code contained in the .asmx file itself.

> **Note** If the code is contained in the .asmx file directly, then ASP.NET will compile it on demand on the server.

The **WebService** processing directive at the top of the .asmx file determines where to find the implementation of the XML Web service. By default, Visual Studio uses code-behind files, such as Service1.asmx.vb or Service1.asmx.cs, when you create an XML Web service with the ASP.NET Web Service project template.

> **Note** Visual Studio does not support cross-language compiling. For example, it is not possible to include a Visual C# XML Web service in a Visual Basic ASP.NET Web Application project, and vice versa.

When you build an XML Web service in managed code, ASP.NET automatically provides the infrastructure and handles the processing of XML Web service requests and responses, including the parsing and creation of SOAP messages.

WebService Processing Directive

At the top of the .asmx page is a **WebService** processing directive, which includes information in the form of attributes regarding the implementation of the XML Web service. This processing directive provides necessary information to the ASP.NET environment, such as which class implements the XML Web service functionality. An example of the **WebService** processing directive follows:

```
' Visual Basic
<%@ WebService Language="vb" Codebehind="Service1.asmx.vb"
    Class="WebService1.Service1" %>

// C#
<%@ WebService Language="c#" Codebehind="Service1.asmx.cs"
    Class="WebService1.Service1" %>
```

The **Language** attribute indicates the programming language used to develop the XML Web service. You can create XML Web services in any .NET-compatible language, such as Visual Basic .NET or Visual C#.

When creating XML Web services in managed code using Visual Studio .NET, the implementation of the XML Web service resides in a code-behind file. The code-behind file is associated with the .asmx page using the **Codebehind** attribute.

> **Note** This attribute helps Visual Studio to manage your XML Web service project and is not required at runtime.

When using the ASP.NET Web Service project template, the **Class** attribute indicates which class in the code-behind file implements the functionality of the XML Web service.

Visual Studio .NET inserts this processing directive automatically into the .asmx file when you use the ASP.NET Web Service project template.

> **Tip** If you choose to rename the class, be sure to change the class name in the **Class** attribute of the **WebService** directive.

> **Note** To view the contents of the .asmx file, in **Solution Explorer**, right-click the .asmx file and click **Open With** on the shortcut menu. In the **Open With** dialog box, select **Source Code (Text) Editor** and then click **Open**.

For more information, see Declaring an XML Web Service.

System.Web.Services.WebService Class

The System.Web.Services.WebService class, which defines the optional base class for XML Web services, provides direct access to common ASP.NET objects, such as those for application and session state. By default, XML Web services created in managed code using Visual Studio inherit from this class. The XML Web service can inherit from this class to gain access to ASP.NET's intrinsic objects, such as Request and Session. For more information, see WebService Class.

If the XML Web service does not inherit from this class, it can access the ASP.NET intrinsic objects from **System.Web.HttpContext.Current**. The class implementing the XML Web service must be public and must have a public default

constructor (a constructor without parameters). This makes it possible for ASP.NET to create an instance of the XML Web service class to process incoming XML Web service requests. For more information, see HttpContext.Current Property.

```
' Visual Basic
Imports System.Web.Services
Public Class Service1
   Inherits System.Web.Services.WebService
   ' Implementation code.
End Class

// C#
using System.Web.Services;
public class Service1 : System.Web.Services.WebService
{
   // Implementation code.
}
```

For more information, see Inheriting from the WebService Class.

WebService Attribute

Each XML Web service requires a unique namespace, which makes it possible for client applications to differentiate among XML Web services that might use the same method name. The default namespace for XML Web services created in Visual Studio .NET is "`http://tempuri.org/WebService1/Service1`" where `WebService1` is the project name and `Service1` is the class name. Although the namespace resembles a typical URL, you should not assume that it is viewable in a Web browser, it is merely a unique identifier.

> **Note** You may want to provide a Web page at that location that contains information about XML Web services you provide.

Using the **WebService** attribute, you can specify the namespace and provide a brief description for the XML Web service. The brief description will appear on the Service help page when you call the XML Web service from a browser without specifying a query string:

```
' Visual Basic
<System.Web.Services.WebService( _
   Namespace:="http://tempuri.org/WebService1/Service1", _
   Description:="A short description of the XML Web service.")> _
Public Class Service1
   Inherits System.Web.Services.WebService
   ' Implementation code.
End Class

// C#
[System.Web.Services.WebService(
   Namespace="http://tempuri.org/WebService1/Service1",
   Description="A short description of the XML Web service.")]
public class Service1 : System.Web.Services.WebService
{
   // Implementation code.
}
```

For more information, see WebServiceAttribute Class and Using the WebService Attribute.

Applying the WebMethod Attribute

To expose a method as part of an XML Web service, you must place a **WebMethod** attribute before the declaration of each public method you want to expose. For more information, see Creating an XML Web Service Method.

```
' Visual Basic
<System.Web.Services.WebMethod()> _
Public Function MyString(ByVal x as string) As String
   ' Implementation code.
End Function
```

```
// C#
[System.Web.Services.WebMethod()]
public string MyString(string x)
{
   //implementation code
}
```

The WebMethod attribute contains several properties for configuring the behavior of the XML Web service. For more information, see WebMethodAttribute Class and Using the WebMethod Attribute. For example, you can use this attribute to provide a brief description that will appear on the associated Service help page:

```
' Visual Basic
<System.Web.Services.WebMethod( _
   Description:="A short description of this method.")> _
Public Function MyString(ByVal x as string) As String
   ' Implementation code.
End Function

// C#
[System.Web.Services.WebMethod(
   Description="A short description of this method.")]
public string MyString(string x)
{
   // Implementation code.
}
```

Separate multiple properties with a comma. For example, to provide a description and to cache the results of an XML Web service for 60 seconds:

```
' Visual Basic
<System.Web.Services.WebMethod( _
   Description:="A short description of this method.", _
           CacheDuration:=60)> _
Public Function MyString(ByVal x as string) As String
   ' Implementation code.
End Function

// C#
[System.Web.Services.WebMethod(
   Description="A short description of this method.",
   CacheDuration=60)]
public string MyString(string x)
{
   // Implementation code.
}
```

Summary

Each XML Web service consists of an .asmx file and an XML Web service class. The .asmx file contains a **WebService** processing directive that references the class. The XML Web service class is public, has a public default constructor, and contains one or more public methods marked with the **WebMethod** attribute. The following diagram shows the relationship between the project, the class, its methods, and the resulting XML Web service.

WebService Classes and Resulting Items

Creating XML Web Services in Managed Code | Code Model for Accessing XML Web Services in Managed Code

Exploring XML Web Service Content

The .asmx file represents the addressable entry point for XML Web services created with managed code. How you access this file through HTTP determines the type of response received.

Service Help Page

When called from a Web browser without supplying a recognized query string, the .asmx file returns an automatically generated Service help page for the XML Web service. This is the equivalent of doing an HTTP GET on the .asmx file.

This Service method help page provides a list of the methods the XML Web service provides and that you can access programmatically. This page contains links for each method that will take you to additional information about that method. In addition, this page contains a link to the XML Web service description document.

To access the Service help page

- In your browser's Address field, type the base URL for the XML Web service by using this format:

```
http://servername/projectname/xmlwebservicename.asmx
```

Parameter	Value
servername	The server on which the XML Web service resides.
projectname	The name of the project for your XML Web service and any additional directory information needed to access the .asmx file for your XML Web service.
webservicename.asmx	The name of the .asmx file for the XML Web service.

For example, to access an XML Web service named Service1.asmx that is part of a project named WebService1 on your local machine, you would enter the following:

```
http://localhost/XmlWebService1/Service1.asmx
```

Service Method Help Page

The Service method Help page provides additional information that relates to that particular XML Web service method.

The page provides the ability to invoke the method using the HTTP-POST protocol. However, the XML Web service method must support the HTTP-POST protocol to enable this functionality.

At the bottom of the page, the Service method help page provides sample request and response messages for the protocols the XML Web service method supports.

Service Description

The Service Help page also provides a link to the XML Web service's service description, which is a formal definition of the XML Web service's capabilities. The service description is a document that uses the Web Services Description Language (WSDL) grammar. The service description defines the contract for the message formats clients need to follow when exchanging messages with the XML Web service. For more information, see XML Web Service Description.

To access the service description

- In your browser's Address field, type the base URL for the XML Web service and provide the WSDL query string by using this format:

```
http://servername/projectname/xmlwebservicename.asmx?WSDL
```

Parameter	Value
servername	The server on which the XML Web service resides.
projectname	The name of the project for your XML Web service and any additional directory information needed to access the .asmx file for your XML Web service.

webservicenam e.asmx	The name of the .asmx file for the XML Web service.

For example, to access the service description of an XML Web service named Service1.asmx that is part of a project named WebService1 on your local machine, you would enter the following:

```
http://localhost/XmlWebService1/Service1.asmx?WSDL
```

Accessing XML Web Services from a Web Browser

You can access an XML Web service that supports the HTTP-GET protocol from a Web browser. By default, XML Web services that you create in Visual Studio by using the ASP.NET Web Service project template support HTTP-GET, HTTP-POST, and HTTP-SOAP. Not all protocols can support all methods. In general, the HTTP-GET and HTTP-POST protocols are more restricted than HTTP-SOAP in the data types they can support.

To access an XML Web service from a Web Browser

- In your browser's Address field, type the base URL for the XML Web service with the method name and parameters in the query string by using the following format:

```
http://servername/projectname/xmlwebservicename.asmx/methodname?parametername0=value0&par
ametername1=value1&...&parameternamen=valuen
```

Parameter	Value
servername	The server on which the XML Web service resides.
projectname	The name of the project for your XML Web service and any additional directory information needed to acce ss the .asmx file for your XML Web service.
webservicenam e.asmx	The name of the .asmx file for the XML Web service.
methodname	The case-sensitive name of the Web method.
parameternam e	The names of the Web method parameters.
value	The URL encoded values of each of the Web method parameters.

For example, to access the **ReturnThisString** method of an XML Web service named **Service1.asmx** with a parameter named **MyString** set to a value of "This is my test string" and that is part of a project named **WebService1** on your local machine, you would enter the following:

```
http://localhost/XmlWebService1/Service1.asmx/ReturnThisString?MyString=This+is+my+test+s
tring
```

Creating XML Web Services in Managed Code | XML Web Service Description

Creating ASP.NET Web Service Projects

You can start a project that includes the necessary files for creating an XML Web service in either Visual Basic or Visual C# by using the project templates provided by Visual Studio.

To create an XML Web service project

1. On the **File** menu, point to **New**, and then click **Project**.
2. In the **New Project** dialog box, select either the **Visual Basic Projects** or the **Visual C# Projects** folder.
3. Click the **ASP.NET Web Service** icon.
4. Enter the address of the Web server on which you will develop the XML Web service. For example, use "http://MyServer/Application" or simply "http://MyServer" to develop in the root directory.

   > **Note** For some project types, the Name textbox is unavailable because specifying the location sets the project name instead. For example, Web applications and XML Web services are located on a Web server and derive their name from the virtual directory specified on that server.

5. Click **OK** to create the project.

Visual Studio automatically creates the necessary files and references to support an XML Web service. When completed, the IDE displays the .asmx file in Design view. For more information, see ASP.NET Web Service Projects in Visual Studio.

Creating XML Web Services in Managed Code | Working with Web Projects

Adding an XML Web Service to an Existing Web Project in Managed Code

You can add an XML Web service to an existing Web project in Visual Studio.

To add a new XML Web service to an existing Web project

1. In **Solution Explorer**, select the project to which you want to add an XML Web service.
2. On the **Project** menu, click **Add Web Service**. Alternatively, right-click the project name, point to **Add** and then click **Add Web Service**.
3. The **Add New Item** dialog appears. By default, the dialog box selects the **ASP.NET Web Service** template and supplies a name for the new XML Web service in the **Name** box.
4. Click **Open** to add the XML Web service to your project.

Visual Studio automatically creates the necessary files and references to support an XML Web service. When completed, the IDE displays the .asmx file in Design view. For more information, see ASP.NET Web Service Projects in Visual Studio.

To add an existing XML Web service to an existing Web project

You can also add an existing XML Web service to an existing Web project in Visual Studio. This process is limited to XML Web services written in the same programming language as your existing Web project. For more information, see Adding Existing Items to a Project.

1. In **Solution Explorer**, select the project to which you want to add an existing XML Web service.
2. On the **Project** menu, select **Add Existing Item**. Alternatively, right-click the project name, point to **Add** and then click **Add Existing Item**. The **Add Existing Item** dialog box appears.
3. In the **Files of type** list, click **Web Files**.
4. Select the .asmx file for the XML Web service you want to add.
5. Click **Open** to add the XML Web service to your project.

Visual Studio adds the .asmx file and its associated code-behind file to your project. For more information, see ASP.NET Web Service Projects in Visual Studio.

See Also

Creating XML Web Services in Managed Code | Working with Web Projects | Adding New Project Items

Using the WebService Attribute

You can use the **WebService** attribute to specify the namespace, which defaults to "`http://tempuri.org`", and description text for the XML Web service. By default the ASP.NET Web Service project template does not generate a class that includes this attribute. Separate multiple properties with a comma.

For more information, see Declaring an XML Web Service.

To apply the WebService attribute

- Insert the **WebService** attribute before the class declaration and set the **Namespace** and **Description** properties as shown below:

```
' Visual Basic
<System.Web.Services.WebService( _
   Namespace:="http://servername/xmlwebservices/", _
   Description:="Some descriptive text could go here.")> _
Public Class Service1
    Inherits System.Web.Services.WebService
    ' Implementation code.
End Class

// C#
[System.Web.Services.WebService(
   Namespace="http://servername/xmlwebservices/",
   Description="Some descriptive text could go here.")]
public class Service1 : System.Web.Services.WebService
{
    // Implementation code.
}
```

See Also

Creating XML Web Services in Managed Code | WebServiceAttribute Class

Inheriting from the WebService Class

By default, XML Web services created by using the ASP.NET Web Service project template inherit from the **System.Web.Services.WebSerivce** class. Inheriting this class makes it possible for the XML Web service to access the ASP.NET intrinsic objects, such as Application and Session. For more information, see Inheritance (Visual Basic .NET) or 10.2.1 Inheritance (C#)

> **Note** If your class does not inherit from the **WebService** class, the Component Designer for the XML Web service will not be available.

If the XML Web service does not inherit from this class, it can access the ASP.NET intrinsic objects from **System.Web.HttpContext.Current**. This can be the case when your XML Web service needs to inherit from a custom base class. The class implementing the XML Web service must be public and must have a public default constructor (a constructor without parameters). This makes it possible for ASP.NET to create an instance of the XML Web service class to process incoming XML Web service requests. For more information, see HttpContext.Current Property.

To inherit from the System.Web.Services.WebService class

- You can inherit from the **System.Web.Services.WebService** class as shown in the example below:

```
' Visual Basic
Public Class Service1
    Inherits System.Web.Services.WebService
    <System.Web.Services.WebMethod( _
       Description:="Get SessionID", _
       EnableSession:=True)> _
    Public Function GetSessionID() As String
        GetSessionID = Me.Session.SessionID
    End Function
End Class

// C#
public class Service1 : System.Web.Services.WebService
{
    [System.Web.Services.WebMethod(
       Description="Get SessionID",
       EnableSession=true)]
    public string GetSessionID()
    {
        return this.Session.SessionID;
    }
}
```

Creating XML Web Services in Managed Code | WebService Class | HttpContext.Current Property

Creating an XML Web Service Method

When you create an XML Web service in managed code, you indicate the methods that are available through that XML Web service by placing the **WebMethod** attribute before the method declaration of a **Public** method. **Private** methods cannot serve as the entry point for an XML Web service although they can be in the same class and the XML Web service code can call them. The **WebMethod** attribute must be applied to each public method that is available as part of the XML Web service. For more information, see Defining XML Web Service Methods.

The procedures below assume that you are working with public methods of a class that is the implementation of an XML Web service. For more information, see Code Model for XML Web Services in Managed Code.

To create an XML Web service method

1. Select your .asmx file (for example, **Service1.asmx)** in **Solution Explorer**. On the **View** menu, click **Code** to view the code-behind file. Alternatively, right-click the .asmx file in **Solution Explorer** and then click **View Code** on the shortcut menu.

   > **Note** **Solution Explorer** hides code-behind files by default. Click **Show All Files** in the **Solution Explorer** toolbar to see hidden files. Alternatively, on the **Project** menu, click **Show All Files**.

   The .asmx file specifies the class that is the implementation of the XML Web service in the **Class** property of the .asmx file's **WebService** processing directive. Following is an example:

   ```
   ' Visual Basic
   <%@ WebService Language="vb" Codebehind="Service1.asmx.vb"
       Class="WebService1.Service1" %>

   // C#
   <%@ WebService Language="c#" Codebehind="Service1.asmx.cs"
       Class="WebService1.Service1" %>
   ```

   If you rename the class, be sure to change the class name in the **Class** property of the **WebService** directive as well.

2. Add a public method to the class specified in the **Class** property of the .asmx file's **WebService** processing directive as shown below:

   ```
   ' Visual Basic
   Public Class Service1
       Inherits System.Web.Services.WebService
       <System.Web.Services.WebMethod()> _
       Public Function ConvertTemperature(ByVal dFahrenheit As Double) _
                                          As Double
           ConvertTemperature = ((dFahrenheit - 32) * 5) / 9
       End Function
   End Class

   // C#
   public class Service1 : System.Web.Services.WebService
   {
       [System.Web.Services.WebMethod()]
       public double ConvertTemperature(double dFahrenheit)
       {
          return ((dFahrenheit - 32) * 5) / 9;
       }
   }
   ```

   Attaching the **WebMethod** attribute to a **Public** method indicates that you want the method exposed as part of the XML Web service. For more information, see Code Model for XML Web Services in Managed Code.

See Also

Using the WebMethod Attribute

Attaching the **WebMethod** attribute to a **Public** method indicates that you want the method exposed as part of the XML Web service. You can also use the properties of this attribute to further configure the behavior of the XML Web service method. For more information, see Code Model for XML Web Services in Managed Code.

The WebMethod attribute provides the following properties:

- BufferResponse
- CacheDuration
- Description
- EnableSession
- MessageName
- TransactionOption

BufferResponse

The **BufferResponse** property of the **WebMethod** attribute enables buffering of responses for an XML Web service method. When set to **true**, the default setting, ASP.NET buffers the entire response before sending it down to the client. The buffering is very efficient and helps improve performance by minimizing communication between the worker process and the IIS process. When set to **false**, ASP.NET buffers the response in chunks of 16KB. Typically, you would set this property to **false** only if you did not want the entire contents of the response in memory at once. For example, you are writing back a collection that is streaming its items out of a database. Unless otherwise specified, the default value is **true**. For more information, see WebMethodAttribute.BufferResponse Property.

To buffer the response of an XML Web service method

- Use the **BufferResponse** property of the **WebMethod** attribute, as shown below:

```
' Visual Basic
Public Class Service1
    Inherits System.Web.Services.WebService
    <System.Web.Services.WebMethod(BufferResponse:=False)> _
    Public Function GetBigData() As DataSet
        'implementation code
    End Function
End Class

// C#
public class Service1 : System.Web.Services.WebService
{
    [System.Web.Services.WebMethod(BufferResponse=false)]
    public DataSet GetBigData()
    {
       //implementation code
    }
}
```

CacheDuration

The **CacheDuration** property of the **WebMethod** attribute enables caching of the results for an XML Web service method. ASP.NET will cache the results for each unique parameter set. The value of this property specifies how many seconds ASP.NET should cache the results. A value of zero disables the caching of results. Unless otherwise specified, the default value is zero. For more information, see WebMethodAttribute.CacheDuration Property.

To cache the results of an XML Web service method

- Use the **CacheDuration** property of the **WebMethod** attribute, as shown below:

```
' Visual Basic
Public Class Service1
```

```
    Inherits System.Web.Services.WebService
    <System.Web.Services.WebMethod(CacheDuration:=60)> _
    Public Function ConvertTemperature(ByVal dFahrenheit As Double) _
                                       As Double
        ConvertTemperature = ((dFahrenheit - 32) * 5) / 9
    End Function
End Class

// C#
public class Service1 : System.Web.Services.WebService
{
    [System.Web.Services.WebMethod(CacheDuration=60)]
    public double ConvertTemperature(double dFahrenheit)
    {
       return ((dFahrenheit - 32) * 5) / 9;
    }
}
```

Description

The **Description** property of the **WebMethod** attribute supplies a description for an XML Web service method that will appear on the Service help page. Unless otherwise specified, the default value is an empty string. For more information, see WebMethodAttribute.Description Property.

To supply a description for an XML Web service method

- Use the **Description** property of the **WebMethod** attribute, as shown below:

```
' Visual Basic
Public Class Service1
    Inherits System.Web.Services.WebService
    <System.Web.Services.WebMethod( _
       Description:="This method converts a temperature " & _
       "in degrees Fahrenheit to a temperature in degrees Celsius.")> _
    Public Function ConvertTemperature(ByVal dFahrenheit As Double) _
                                       As Double
        ConvertTemperature = ((dFahrenheit - 32) * 5) / 9
    End Function
End Class

// C#
public class Service1 : System.Web.Services.WebService
{
    [System.Web.Services.WebMethod(
       Description="Converts F to C a temperature in " +
       "degrees Fahrenheit to a temperature in degrees Celsius.")]
    public double ConvertTemperature(double dFahrenheit)
    {
       return ((dFahrenheit - 32) * 5) / 9;
    }
}
```

EnableSession

The **EnableSession** property of the **WebMethod** attribute enables session state for an XML Web service method. Once enabled, the XML Web service can access the session state collection directly from **HttpContext.Current.Session** or with the **WebService.Session** property if it inherits from the **WebService** base class. Unless otherwise specified, the default value is **false**. For more information, see WebMethodAttribute.EnableSession Property.

To enable session state in an XML Web service method

- Use the **EnableSession** property of the **WebMethod** attribute, as shown below:

```
' Visual Basic
Public Class Service1
    Inherits System.Web.Services.WebService
    <System.Web.Services.WebMethod(EnableSession:=True)> _
    Public Function ConvertTemperature(ByVal dFahrenheit As Double) _
                                       As Double
        Session("Conversions") = Session("Conversions") + 1
        ConvertTemperature = ((dFahrenheit - 32) * 5) / 9
    End Function
    <System.Web.Services.WebMethod(EnableSession:=True)> _
    Public Function GetNumberOfConversions() As Integer
        GetNumberOfConversions = Session("Conversions")
    End Function
End Class

// C#
public class Service1 : System.Web.Services.WebService
{
    [System.Web.Services.WebMethod(EnableSession=true)]
    public double ConvertTemperature(double dFahrenheit)
    {
       Session["Conversions"] = (int) Session["Conversions"] + 1;
       return ((dFahrenheit - 32) * 5) / 9;
    }
    [System.Web.Services.WebMethod(EnableSession=true)]
    public int GetNumberOfConversions()
    {
       return (int) Session["Conversions"];
    }
}
```

MessageName

The **MessageName** property of the **WebMethod** attribute enables the XML Web service to uniquely identify overloaded methods using an alias. Unless otherwise specified, the default value is the method name. When specifying the **MessageName**, the resulting SOAP messages will reflect this name instead of the actual method name. For more information, see WebMethodAttribute.MessageName Property.

To supply a message name for an XML Web service method

- Use the **MessageName** property of the **WebMethod** attribute, as shown below:

```
' Visual Basic
Public Class Service1
    Inherits System.Web.Services.WebService
    <System.Web.Services.WebMethod(MessageName:="AddDoubles")> _
    Public Function Add(ByVal dValueOne As Double, _
                        ByVal dValueTwo As Double) As Double
        Add = dValueOne + dValueTwo
    End Function
    <System.Web.Services.WebMethod(MessageName:="AddIntegers")> _
    Public Function Add(ByVal iValueOne As Integer, _
                        ByVal iValueTwo As Integer) As Integer
        Add = iValueOne + iValueTwo
    End Function
End Class

// C#
```

```
public class Service1 : System.Web.Services.WebService
{
    [System.Web.Services.WebMethod(MessageName="AddDoubles")]
    public double Add(double dValueOne, double dValueTwo)
    {
       return dValueOne + dValueTwo;
    }
    [System.Web.Services.WebMethod(MessageName="AddIntegers")]
    public int Add(int iValueOne, int iValueTwo)
    {
       return iValueOne + iValueTwo;
    }
}
```

The SOAP request message for the method that adds doubles, **AddDoubles**, will resemble the following:

```
POST /myWebService/Service1.asmx HTTP/1.1
Host: localhost
Content-Type: text/xml; charset=utf-8
Content-Length: length
SOAPAction: "http://tempuri.org/AddDoubles"

<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xmlns:xsd="http://www.w3.org/2001/XMLSchema"
 xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
  <soap:Body>
    <AddDoubles xmlns="http://tempuri.org/">
      <dValueOne>double</dValueOne>
      <dValueTwo>double</dValueTwo>
    </AddDoubles>
  </soap:Body>
</soap:Envelope>
HTTP/1.1 200 OK
Content-Type: text/xml; charset=utf-8
Content-Length: length
```

The SOAP response message for the method that adds doubles, **AddDoubles**, will resemble the following:

```
<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xmlns:xsd="http://www.w3.org/2001/XMLSchema"
 xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
  <soap:Body>
    <AddDoublesResponse xmlns="http://tempuri.org/">
      <AddDoublesResult>double</AddDoublesResult>
    </AddDoublesResponse>
  </soap:Body>
</soap:Envelope>
```

TransactionOption

The **TransactionOption** property of the **WebMethod** attribute enables the XML Web service method to participate as the root object of a transaction. Even though you can set the **TransactionOption** property to any of the values of the **TransactionOption** enumeration, an XML Web service method only has two possible behaviors; it does not participate in a transaction (**Disabled**, **NotSupported**, **Supported**), or it creates a new transaction (**Required**, **RequiresNew**). Unless otherwise specified, the default value is **TransactionOption.Disabled**. For more information, see WebMethodAttribute.TransactionOption Property.

In addition to the prerequisites for any XML Web service method, you need to add a reference to **System.EnterpriseServices.dll**. This namespace contains methods and properties that expose the distributed transaction model found in COM+ Services. The **System.EnterpriseServices.ContextUtil** class lets you vote on the transaction using the **SetAbort** or **SetComplete** methods. For more information, see Participating in Transactions in XML Web Services Created Using ASP.NET and Automatic Transactions and XML Web Services.

To create a new transaction with an XML Web service method

1. Add a reference to **System.EnterpriseServices.dll**. For more information, see Adding and Removing References.
2. Add the **System.EnterpriseServices** namespace to the XML Web service, as shown below:

```
' Visual Basic
Imports System.EnterpriseServices

// C#
using System.EnterpriseServices;
```

3. Use the **TransactionOption** property of the **WebMethod** attribute, as shown below:

```
' Visual Basic
Public Class Service1
    Inherits System.Web.Services.WebService
    <System.Web.Services.WebMethod( _
       TransactionOption:=TransactionOption.RequiresNew)> _
    Public Function DoSomethingTransactional() As String
       'The transaction was successful...
       ContextUtil.SetComplete
       DoSomethingTransactional = ContextUtil.TransactionId.ToString()
    End Function
End Class

// C#
public class Service1 : System.Web.Services.WebService
{
    [System.Web.Services.WebMethod(
       TransactionOption=TransactionOption.RequiresNew)]
    public string DoSomethingTransactional()
    {
       // The transaction was successful...
       ContextUtil.SetComplete();
       return ContextUtil.TransactionId.ToString();
    }
}
```

Debugging XML Web Services in Managed Code

When you are ready to build and run your XML Web service, you must first compile the ASP.NET Web Service project. Once compiled, you can run the XML Web service. For more information, see Debugging Preparation: ASP.NET Web Service Projects.

You can choose from three methods to build and run your XML Web service:

Method	Description
With the debugger	This method starts the default browser and loads the specified start page. Running a page in the debugger makes it possible for you to step through code line-by-line and use additional analysis tools and runtime information. If Visual Studio detects that key files have changed, it will also build the project before launching the browser with the specified start page.
Without the debugger	This method makes it possible for you to run your code as it normally would run outside of the context of development tools, and therefore no runtime information is available through these tools. If Visual Studio detects that key files have changed, it will build the project before launching the browser with the specified start page. However, you can attach the debugger to the process as needed.
View in browser	This method compiles the project and opens a Web page chosen from Solution Explorer. Visual Studio compiles and runs the project in the default browser within Visual Studio.

To build and run an XML Web service with the debugger

1. In **Solution Explorer**, right-click the .asmx file for the XML Web service you wish to run and click **Set As Start Page** on the shortcut menu.
2. On the **Debug** menu, click **Start**.

   This command instructs Visual Studio to run the XML Web service in the debugger.

3. To stop running the form and return to the Code Editor, close the browser, or click **Stop Debugging** on the **Debug** menu.

To build and run an XML Web service without the debugger

1. In Solution Explorer, right-click the .asmx file for the XML Web service you wish to run and click **Set As Start Page** on the shortcut menu.
2. On the **Debug** menu, click **Start Without Debugging**.

   Visual Studio saves all files in the project and then builds it. Once built, Visual Studio launches the default browser and navigates to the project's start page.

3. To stop running the XML Web service and return to the Code Editor, close the browser.

To build and run an XML Web service using the View in Browser option

1. In **Solution Explorer**, right-click the .asmx file for the XML Web service you want to run and click **View in Browser** on the shortcut menu.

   Visual Studio builds the XML Web service and launches the specified start page within the IDE.

2. To stop running the XML Web service and return to the Code Editor, close the browser.

Creating XML Web Services in Managed Code | Debugging Preparation: ASP.NET Web Service Projects

Deploying XML Web Services in Managed Code

When using Visual Studio .NET to create XML Web services in managed code, you use a standard deployment model: you compile your project and then you deploy the resulting files to a production server. The project .dll file contains the XML Web services code-behind class file (.asmx.vb or .asmx.cs) along with all other class files included in your project, but not the .asmx file itself. You then deploy this single project .dll file to the production server without any source code. When the XML Web service receives a request, the project .dll file is loaded and executed.

Compiling and Deploying an XML Web Service in Managed Code

Suppose you have a simple ASP.NET Web Service project named WebService1 that contains the following:

- An XML Web service entry page named Service1.asmx.
- Some additional modules, named Service1.vb (or .cs) and BusinessLogic.vb (or .cs), which contain business logic.

When you compile the project, the following occurs:

- Visual Studio saves all of the files in the project you modified since the last build.
- Visual Studio copies the Service1.asmx file and the default project files to the development Web server.
- The Service1.asmx.vb (or .asmx.cs) class file, the Global.asax class file, and the BusinessLogic.vb (.cs) class file are compiled into the project .dll file, which is then copied to the server in the default \Bin directory of the target virtual directory. If the project is set to compile a debug version, Visual Studio creates a project .pdb file in the \Bin directory.

> **Note** If compilation errors occur, the deployment will not succeed. For more information, see Debugging XML Web Services in Managed Code.

To deploy the XML Web service to a server other than the development server, you can add a Web Setup project or you can copy the required files to the destination server. To make your XML Web service available to others, you will need to deploy it to a Web server that is accessible to the clients you wish to support. For more information, see Deploying Applications and Components and Copying a Project.

To deploy the XML Web service using a Web Setup project

1. On the **File** menu, point to **Add Project** and then click **New Project**.
2. Select the **Setup and Deployment Projects** folder and then click **Web Setup Project**.
3. In the **Name** box, type a name for your deployment project and then click **OK**.
4. In Solution Explorer, right-click the deployment project. On the shortcut menu, point to **Add**, and then click **Project Output**.
5. In the **Add Project Output Group** dialog box, select **Primary output**, **Debug Symbols**, and **Content Files**. For more information, see Adding and Removing Project Outputs in the File System Editor.
   - The Primary output group consists of the project .dll file and its dependencies.
   - The Debug Symbols group consists of the project PDB file.
   - The Content Files group consists of the remaining files for the XML Web service, such as the .asmx, .asax, and .config files.
6. Click **OK**.

To deploy the XML Web service by copying the project

1. In Solution Explorer, select the project you want to copy.
2. On the **Project** menu, click **Copy Project**.
3. In the **Destination project folder** box, enter the location to which you want to copy the project.
4. Select either **FrontPage** or **File share** to select a **Web access method**. For more information, see Changing Web Project Access Methods.
5. Select **Only files needed to run this application**.
6. Click **OK**.

After deploying your XML Web service, you need to consider how to make it possible for developers to locate it if you intend others to use it. For more information, see Fine-Tuning Discovery Mechanisms.

An XML Web service client is any component or application that references and uses an XML Web service. This does not necessarily need to be a client-based application; in fact, in many cases your XML Web service clients might be other Web applications, such as Web Forms or even other XML Web services.

Code Model for Accessing XML Web Services in Managed Code

An XML Web service client is any component, service, or application that references and utilizes an XML Web service. It is worthwhile to note that XML Web service clients need not be a client-based application, such as a desktop application; in most cases, your XML Web service clients may be other Web applications or even other XML Web services.

When accessing XML Web services in managed code, a proxy class and the .NET Framework handle all of the infrastructure coding. Accessing an XML Web service follows these basic steps:

- Locate the XML Web service you want to access.
- Create a proxy class for the XML Web service by adding a Web reference to your project.
- Reference the proxy class in the client code by including its namespace.
- Create an instance of the XML Web service proxy class in the client code.
- Access the XML Web service using the methods of the proxy.

For more information, see Accessing an XML Web Service in Managed Code or Accessing an XML Web Service Asynchronously in Managed Code.

Locating an XML Web Service and Adding a Web Reference

To simplify the coding model, applications written in managed code use a Web reference to locally represent each XML Web service. You add a Web reference to your project using the Add Web Reference dialog box. This dialog box supports browsing Web addresses for an XML Web service. For more information, see Locating XML Web Services and Web References.

Reference the Proxy Class

The generated proxy class has its own namespace associated with it, and you must add the namespace to your client application before you can create an instance of that class. For more information, see using Directive (C#) or References and the Imports Statement (Visual Basic .NET).

Create an Instance of the Proxy Class

Before you can call any of the methods of the proxy class, you must first create an instance of that class. This process does not differ at all from creating an instance of any other class. For more information, see new (C#) or Object Variable Declaration (Visual Basic .NET).

Access the XML Web Service Using the Proxy

To access an XML Web service method, your client application invokes either the corresponding synchronous method or asynchronous methods of the proxy object. These methods in turn do the necessary work to remote the call over the wire to call the desired XML Web service method. By default, the proxy class uses SOAP to access the XML Web service method, as SOAP supports the richest set of data types of the three supported protocols (HTTP-GET, HTTP-POST, and HTTP-SOAP). For more information, see XML Web Service Wire Formats.

Summary

Using a proxy class that Visual Studio generated directly from the service description of an XML Web service, accessing an XML Web service in managed code is a relatively simple process. The proxy class does the work to transform the method call into a request message and the response message back into a method return value.

The following picture shows the relationship of an application that calls an XML Web service, which in turn calls another XML Web service to obtain pricing information. In this example, the Get Current Prices XML Web service is both an XML Web service provider and an XML Web service consumer.

XML Web Service Clients and XML Web Services

See Also

Locating XML Web Services

Sometimes you may be both the provider and consumer of an XML Web service. In this case, you probably know the location and function of the XML Web service. At other times, you may be accessing an XML Web service provided by someone else. When this occurs, you may not even know if an XML Web service that suits your purposes in fact exists.

To simplify the coding model, applications written in managed code use a Web reference to locally represent each XML Web service. You add a Web reference to your project by using the Add Web Reference dialog box. This dialog box makes it possible for you to browse your local server, the Microsoft UDDI Directory, and the Internet at large. XML Web service providers publicize their XML Web services in XML Web services directories, which is where XML Web service consumers search of XML Web services to consume. For more information, see XML Web Services Directories.

The Add Web Reference dialog box uses the process of XML Web service discovery to locate eligible XML Web services on Web sites to which you navigate in the dialog box. For a given address, it will interrogate the Web site using an algorithm designed to locate XML Web service discovery (DISCO) documents and ultimately, XML Web service description documents that adhere to the grammar of the Web Services Description Language (WSDL). For more information, see XML Web Service Discovery and XML Web Service Description.

After you have located an XML Web service for your application to access by using the Add Web Reference dialog box, clicking the Add Reference button will instruct Visual Studio to download the service description to the local machine and then generate a proxy class for the chosen XML Web service. The proxy class will contain methods for calling each exposed XML Web service method both synchronously and asynchronously. This class is contained in the local .wsdl file's code-behind file. For more information, see Web References and Add Web Reference Dialog Box.

You can use the Web Reference URL property to specify the URL to the XML Web service. The Add Web Reference sets this property by default to the URL of the XML Web service you select, which is a static URL. A Web reference can use either a static URL or a dynamic URL.

If you leave the URL Behavior set to the default value of static, the proxy class sets the URL property using a hard-coded URL when you create an instance of the class.

If you set the URL Behavior property of the Web reference to dynamic, the application obtains the URL at run time from the <appSettings> Element of your application's configuration file. When you specify a dynamic URL after adding a Web reference, Visual Studio updates the proxy class to obtain the URL from the configuration file.

```
<appSettings>
   <add key="myApplication.myServer.Service1"
        value="http://myServer/myXmlWebService/Service1.asmx"/>
</appSettings>
```

When you create an instance of a proxy object, you can also set the URL property of the object in your application.

Regardless of which URL the proxy uses, it must be for an XML Web service that adheres to a WSDL that matches the one used when adding the Web reference. For more information, see Managing Project Web References.

Alternatively, you can generate a proxy class using a tool (XML Web services Description Language Tool) that is similar to the one used by Visual Studio to create a proxy class when adding a Web reference. This is necessary when you are unable to access the XML Web service from the machine on which Visual Studio is installed, such as when the XML Web service is located on a network that will not be accessible to the client until run time. You then manually add the file that the tool generated to your application project. For more information, see Generating an XML Web Service Proxy.

Accessing XML Web Services in Managed Code | Managing Project Web References | Building XML Web Service Clients | Web Services Description Language (WSDL) Explained

Generating an XML Web Service Proxy

To access an XML Web service from a client application, you first add a Web reference, which is a reference to an XML Web service. When you create a Web reference, Visual Studio creates an XML Web service proxy class automatically and adds it to your project. This proxy class exposes the methods of the XML Web service and handles the marshalling of appropriate arguments back and forth between the XML Web service and your application. Visual Studio uses the Web Services Description Language (WSDL) to create the proxy. For more information, see XML Web Services Infrastructure.

You can use the Web Reference URL property to specify the URL to the XML Web service. The Add Web Reference sets this property by default to the URL of the XML Web service you select, which is a static URL. A Web reference can use either a static URL or a dynamic URL. If you set the URL Behavior property of the Web reference to dynamic, the application obtains the URL at run time from the <appSettings> Element section of your application's configuration file. For more information, see Managing Project Web References.

After adding a Web reference to a client application, you can invoke the exposed methods of that XML Web service and access the results just as you would any other method of a component. For more information, see Web References.

If you are unable to add a Web reference, such as when the XML Web service is not accessible from the machine on which you are using Visual Studio, you can use the XML Web Services Description Language Tool (Wsdl.exe) to generate an XML Web service client proxy class. For more information, see Creating an XML Web Service Proxy.

Accessing an XML Web Service in Managed Code

Accessing an XML Web service from managed code is a straightforward process. First, you add a Web reference to your project for the XML Web service you wish to access. The Web reference creates a proxy class with methods that serve as proxies for each exposed method of the XML Web service. Next, you add the namespace for the Web reference. Finally, you create an instance of the proxy class and then access the methods of that class as you would the methods of any other class. For more information, see Code Model for Accessing XML Web Services in Managed Code.

By default, adding a Web reference also adds methods to the proxy class for accessing the XML Web service asynchronously. For more information, see Accessing an XML Web Service Asynchronously in Managed Code.

To access an XML Web service in managed code

1. Create the application from which you want to access an XML Web service. This application could even be another XML Web service.
2. Add a Web reference for the XML Web service with which your application will interact. For instructions, see Adding and Removing Web References.
3. Create an instance of the proxy object in your client code where you want to access the XML Web service.
4. Access the methods of the XML Web service as you would any other component.

   In the example code below, the client application (**Application1**) is accessing an XML Web service for which it has a Web reference (**Converter**) that contains a proxy class (**Service1**), which has a method (**ConvertTemperature**) for calling the XML Web service. The two lines of code in bold represent the code that is necessary to access the XML Web service.

```
' Visual Basic
Imports System
Module Module1
    Sub Main()
        Dim cService As New Converter.Service1()
        Dim dFahrenheit As Double
        Dim dCelsius As Double
        Console.Write("Temperature in degrees Fahrenheit: ")
        dFahrenheit = Convert.ToDouble(Console.ReadLine())
        dCelsius = cService.ConvertTemperature(dFahrenheit)
        Console.Write("Temperature in degrees Celsius: ")
        Console.WriteLine(dCelsius.ToString())
    End Sub
End Module

// C#
using System;
namespace Application1
{
   class Class1
   {
      static void Main()
      {
         Converter.Service1 cService = new Converter.Service1();
         Console.WriteLine("Temperature in degrees Fahrenheit: ");
         double dFahrenheit = Convert.ToDouble(Console.ReadLine());
         double dCelsius = cService.ConvertTemperature(dFahrenheit);
         Console.Write("Temperature in degrees Celsius: ");
         Console.WriteLine(dCelsius.ToString());
      }
   }
}
```

Accessing an XML Web Service Asynchronously in Managed Code

When adding a Web reference, Visual Studio generates a proxy class that is capable of calling an XML Web service both synchronously and asynchronously. By using an asynchronous method, you can continue to use the calling thread while waiting for the XML Web service to respond. This makes it possible for you to efficiently use the existing set of threads in the client application, which can be critical if the client is a Web application. The XML Web service does not require special configuration to support asynchronous calls nor does it know in which mode the client is calling it because the request and response message behavior is the same for synchronous and asynchronous calls. Client-side asynchronous calls simply uses a system I/O completion port to efficiently wait for the server's response.

For each synchronous method, the generated proxy class also contains a corresponding *Begin* and *End* method. Therefore, if the name of the XML Web service method is **ConvertTemperature**, the name of the synchronous method in the proxy class is also **ConvertTemperature** and the additional proxy methods to support asynchronous calls are **BeginConvertTemperature** and **EndConvertTemperature**.

Calling an XML Web service asynchronously is a two-step operation. The first step, calling the *Begin* method, initiates the XML Web service call. The second step, calling the *End* method, completes the XML Web service call and returns the XML Web service response.

The *Begin* method returns a **System.Web.Services.Protocols.WebClientAsyncResult** object. This object, which implements **System.IAsyncResult**, serves two purposes. First, it provides status about the pending asynchronous call. For example, the **IsCompleted** property indicates if the operation has completed. Second, by passing this object to the *End* method, the proxy can identify which request you would like to complete. This is important because you can make multiple asynchronous calls simultaneously.

There are several ways to determine when the asynchronous XML Web service call has completed:

- The first is to supply a callback delegate to the *Begin* method. After the XML Web service returns its response, a thread will call the callback from the thread pool; this is likely to be a different thread than the one that you used to call the *Begin* method. Typically, you will then call the *End* method inside that callback. Using the callback is the most efficient way to manage usage of your threads since callback functions do not block threads while waiting for the response.
- The second is to wait using one of the **WaitHandle** methods of the **IAsyncResult.AsyncWaitHandle** object. When using the methods of the **WaitHandle** class, the client can also specify a timeout after which it will abandon waiting for results from the XML Web services it called.
- The third is to poll the value of **IAsyncResult.IsCompleted**. When this property returns true, the XML Web service response is available.
- The fourth is to simply call the *End* method directly. This method will not return until the asynchronous operation is complete since it uses the **IAsyncResult.AsyncWaitHandle**.

The **WaitHandle** class makes it possible for clients to make asynchronous call and wait for:

- a single XML Web service (**WaitHandle.WaitOne**),
- the first of many XML Web services (**WaitHandle.WaitAny**), or
- all of many XML Web services (**WaitHandle.WaitAll**) to return results.

If you are making multiple asynchronous XML Web service calls simultaneously, then you might want to use the **WaitHandle.WaitAll** method to block the thread until all calls have completed. If you want to process the results as they arrive, you can use the **WaitHandle.WaitAny** method. This method will indicate that one of the operations has completed and will identify the completed operation.

When accessing XML Web services asynchronously from a Web application, using the methods of the **WaitHandle** class is the preferred method. Otherwise, if execution in the Web application completes before the asynchronous process calls the callback function, as described in the previous section, it may never have the opportunity to do so if the original function's completion results in the destruction of the instance of the Web Form.

If you want to abort an asynchronous XML Web service call, cast the **IAsyncResult** returned from the *Begin* method to **WebClientAsyncResult** and call its **Abort** method.

For more information, see Communicating with XML Web Services Asynchronously.

To call an XML Web service asynchronously using a callback function in managed code

1. Create the application from which you want to access an XML Web service. This application could even be another XML Web service.
2. Add a Web reference for the XML Web service with which your application will interact. For instructions, see Adding and Removing Web References.
3. Implement a callback function. The callback function contains the call to the *End* method of the XML Web service method.
4. Create an instance of the proxy object in your client code where you want to access the XML Web service.
5. Call the *Begin* method of the XML Web service method.
6. Continue doing any other processing in the client application.
7. After the XML Web service finishes processing and returns the results to the proxy, the proxy will call the callback function.

The code shown below is from a Windows application that is accessing an XML Web service for which it has a Web reference (**Translator**) that contains a proxy class (**Service1**), which has a *Begin* method (**BeginLongProcess**) for calling the XML Web service asynchronously and an *End* method (**EndLongProcess**) for completing the call and obtaining the results. In this example, the XML Web service accepts a string, performs some time-consuming translation, and then returns the result. After initiating the asynchronous call to the XML Web service method, the event handler **button1_Click** returns control to the client. When the XML Web service returns its results, it calls the callback function.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, _
                          ByVal e As System.EventArgs) _
                          Handles Button1.Click

   Dim cService As New Translator.Service1()

   ' cb is essentially a function pointer to ServiceCallback.
   Dim cb As New AsyncCallback(AddressOf ServiceCallback)

   ' Call the Begin method of the proxy class to initiate the
   ' asynchronous call to the XML Web service method.
   cService.BeginLongProcess(TextBox1.Text, cb, cService)

End Sub

Public Sub ServiceCallback(ByVal ar As IAsyncResult)

   Dim cService As Translator.Service1

   ' Retrieve the original state for the proxy.
   cService = ar.AsyncState

   ' Retrieve results by calling the End method of the proxy class.
   TextBox2.Text = cService.EndLongProcess(ar)

End Sub

// C#
private void button1_Click(object sender, System.EventArgs e)
{
   Translator.Service1 cService = new Translator.Service1();

   // cb is essentially a function pointer to ServiceCallback.
   AsyncCallback cb = new AsyncCallback(ServiceCallback);

   // Call the Begin method of the proxy class to initiate the
   // asynchronous call to the XML Web service method.
   cService.BeginLongProcess(textBox1.Text, cb, cService);
}
```

```
public void ServiceCallback(IAsyncResult ar)
{
   // Retrieve the original state for the proxy.
   Translator.Service1 cService = (Translator.Service1)ar.AsyncState;

   // Retrieve results by calling the End method of the proxy class
   textBox2.Text = cService.EndLongProcess(ar);
}
```

To call an XML Web service asynchronously using a WaitHandle in managed code

1. Create the application from which you want to access an XML Web service. This application could even be another XML Web service.
2. Add a Web reference for the XML Web service with which your application will interact. When you add a Web reference, Visual Studio creates a proxy class that contains methods for accessing each exposed method of that XML Web service. For instructions, see Adding and Removing Web References.

   To access the XML Web service, you must create an instance of this proxy class and then interact with the methods just as you would with the methods of any other instance of a class.

3. Include the namespace **System.Threading**. You will need this namespace to access the **WaitHandle** class.
4. Create an instance of the proxy object in your client code where you want to access the XML Web service.
5. Create an interface to an **AsyncResult** by calling the *Begin* method of the XML Web service method, which returns a type that implements **IAsyncResult** interface.
6. Continue doing any other processing in the client application.
7. When you reach a point that you require the results from the XML Web service, use a **WaitHandle** to halt processing and wait for the results.
8. Once the XML Web service finishes processing and returns the results to the proxy, the proxy will call the callback function.

   The code shown below is from a Web application that is accessing an XML Web service for which it has a Web reference (**Translator**) that contains a proxy class (**Service1**), which has a *Begin* method (**BeginLongProcess**) for calling the XML Web service asynchronously and an *End* method (**EndLongProcess**) for completing the call and obtaining the results. In this example, the XML Web service accepts a string, performs some time-consuming translation, and then returns the result. After initiating the asynchronous call to the XML Web service method, the client application continues with some additional processing and then waits for the XML Web service to return. When the XML Web service returns, processing continues.

```
' Visual Basic
Private Sub Button1_Click(ByVal sender As System.Object, _
                          ByVal e As System.EventArgs) _
                          Handles Button1.Click

   Dim cService As New Translator.Service1()
   Dim ar1 As IAsyncResult
   Dim ar2 As IAsyncResult

   ' Call the Begin method of the proxy class to initiate the
   ' asynchronous call to the XML Web service method.
   ar1 = cService.BeginLongProcess(TextBox1.Text, Nothing, Nothing)
   ar2 = cService.BeginLongProcess(TextBox3.Text, Nothing, Nothing)

   '...
   ' Keep processing.
   '...

   Dim wh() As WaitHandle = {ar1.AsyncWaitHandle, ar2.AsyncWaitHandle}

   ' Waits for both async XML Web service calls to finish.
   WaitHandle.WaitAll(wh)
```

```
    ' Retrieves the results by calling the End method of the proxy
    ' class.
    TextBox2.Text = cService.EndLongProcess(ar1)
    TextBox4.Text = cService.EndLongProcess(ar2)
End Sub

// C#
private void Button1_Click(object sender, System.EventArgs e)
{
    Translator.Service1 cService = new Translator.Service1();
    IAsyncResult ar1 = cService.BeginLongProcess(TextBox1.Text,
                                                 null, null);
    IAsyncResult ar2 = cService.BeginLongProcess(TextBox3.Text,
                                                 null, null);

    //...
    // Keep processing.
    //...

    WaitHandle[] wh = {ar1.AsyncWaitHandle, ar2.AsyncWaitHandle};

    // Waits for both async XML Web service calls to finish.
    WaitHandle.WaitAll(wh);

    // Retrieves the results by calling the End method of the proxy
    // class.
    TextBox2.Text = cService.EndLongProcess(ar1);
    TextBox4.Text = cService.EndLongProcess(ar2);
}
```

Creating Windows Applications Portal

You start to create traditional Windows applications and client/server applications by designing your forms with the Windows Forms Designer. You assign characteristics to the forms and put controls on them, then write code to augment the functionality of the controls and forms. You can also inherit from forms.

The Help topics about this subject are located in another part of the Visual Studio table of contents, under the section named "Developing with Visual Studio .NET." The links below jump to Help topics in that section on creating Windows applications.

In the Visual Studio Documentation on Windows Applications

Code for Windows Forms Applications
Gives links to topics that demonstrate how to perform common programming tasks in Windows Forms applications.
Introduction to Windows Applications
Discusses the particulars of Windows application creation with Visual Studio .NET
Windows Forms Walkthroughs
Provides step-by-step instructions for creating a number of Windows applications.
Windows Forms
Provides links to topics about the technologies and tools for creating Windows applications.
Windows Forms Controls
Provides links to topics about the controls designed specifically to work with Windows Forms.
Windows Service Applications
Describes how to create long-running executables.

In the Visual Basic and Visual C# Documentation

Visual Basic Code Example Topics
Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.
Decision Chart
Provides an interactive guide to help you choose which approach or technology to use, as well as links to more information.
Windows Forms and Web Forms Recommendations
Discusses considerations for choosing between the two forms packages.
Windows Applications Namespaces in Visual Studio
Provides links to namespaces relevant to Windows Forms.

.NET Framework Class Library in Visual Studio

The .NET Framework class library is comprised of namespaces. Each namespace contains types that you can use in your program: classes, structures, enumerations, delegates, and interfaces.

When you create a Visual Basic or Visual C# project in Visual Studio, the most common base class DLLs (assemblies) are already referenced. However, if you need to use a type that is in a DLL not already referenced, you will need to add a reference to the DLL. For more information, see Adding and Removing References.

The topics below provide the following information:

- Lists of the most important namespaces for each feature area.
- Links to reference topics in the .NET Framework about each major namespace.
- Links to procedural and conceptual topics about how to use those namespaces in your Visual Basic .NET and Visual C# .NET applications.

In This Section

Introduction to the .NET Framework Class Library in Visual Studio
Explains namespaces and assemblies.
Programming Basics Namespaces in Visual Studio
Covers the .NET namespaces for collections, character encodings, file I/O, and threading.
Data Namespaces in Visual Studio
Covers the namespaces in the .NET Framework for manipulating and accessing data from traditional data sources and from standards-based XML.
Web Namespaces in Visual Studio
Covers .NET namespaces for ASP.NET Web applications and XML Web services.
Windows Applications Namespaces in Visual Studio
Covers the namespaces in the .NET Framework for creating rich Windows applications and graphics with Windows Forms.
Component Model Namespaces in Visual Studio
Covers the namespaces for implementing the run-time and design-time behavior of components and controls.
Framework Services Namespaces in Visual Studio
Covers the namespaces for interacting with a variety of back-end server resources.
Security Namespaces in Visual Studio
Covers the namespaces that provide the underlying structure of the .NET Framework security system and that implement ASP.NET security in Web applications.
Network Namespaces in Visual Studio
Covers the namespace that provides a simple programming interface to many of the protocols found on the network.
Configuration Namespaces in Visual Studio
Covers the namespaces that work with .NET Framework configuration settings and handle errors in configuration files, and that allow you to write custom installers for components.
Globalization and Localization Namespaces in Visual Studio
Provides links to the namespaces in the .NET Framework that are designed for developing world-ready applications.
Reflection Namespaces in Visual Studio
Covers the namespace that provides a managed view of loaded types, methods, and fields, with the ability to dynamically create and invoke types.
Visual Basic Runtime Namespace in Visual Studio
Describes the modules, enumerations, and attributes that provide the properties, functions, and constants you can use in Visual Basic .NET applications.

Related Sections

Inside the .NET Framework
Provides links to essential information about the common language runtime, assemblies, common type system, metadata, interoperability, security, and other features of the .NET Framework.
Class Library (.NET Framework)
Describes the functionality provided by the types (classes, structures, enumerations, delegates, and interfaces) in the .NET Framework and lists the base data types provided by the **System** namespace.
Microsoft .NET Web site (http://www.microsoft.com/net/)
Provides the latest information and resources about .NET.
Adding and Removing References

Explains how to reference external projects and .NET and COM components so that you can make use of them in your application.

Assemblies

Provides links to topics that explain what assemblies do and how to use them.

Introduction to the .NET Framework Class Library in Visual Studio

A key feature of the .NET Framework is the base class library. For more information about the common language runtime, the class library, the common language specification (CLS), and other features of the .NET Framework, see Inside the .NET Framework.

Namespaces

The .NET Framework class library is comprised of namespaces. Each namespace contains types that you can use in your program: classes, structures, enumerations, delegates, and interfaces. For an overview of the namespaces, see Class Library.

Namespaces provide scope: Two classes with the same name can be used in your program as long as they are in different namespaces and as long as you qualify the names to the namespaces. The namespace name is part of the fully qualified name of the type (*namespace.typename*).

All namespaces shipped by Microsoft begin with one of two names: System or Microsoft.

Managed DLLs (Assemblies)

The functionality of the .NET Framework class library is not contained in a single DLL. By putting the functionality of the base classes in multiple DLLs, a managed program does not need to load, at start up, a large DLL, but, rather, one or more smaller DLLs. This reduces the startup time for a program.

You can use namespaces that are defined in your project. However, you will commonly use types in namespaces that reside in a managed DLL. A managed DLL is also called an *assembly*.

When you create a Visual Basic or Visual C# project in Visual Studio, the most common base class DLLs (assemblies) are already referenced. However, if you need to use a type that is in a DLL not already referenced, you will need to add a reference to the DLL. The Add Reference dialog box allows you to add an assembly.

Namespaces and Assemblies: Usage Summary

The following is a summary of how you will commonly use managed DLLs (assemblies), namespaces, and the types in the namespaces:

1. Locate a class that provides the functionality you need. For more information, see .NET Framework Class Library in Visual Studio and Common Tasks in Visual Basic and Visual C#.
2. In the documentation overview of the type, note the name of the type's assembly and namespace.
3. See if the assembly is already referenced in your project. Open **Solution Explorer** and look under the **References** node.
4. If you do not see an assembly reference, right-click the **References** node and select **Add Reference**. For more information, see Adding and Removing References.
5. After you have an assembly reference, you can access the types in the assembly.

> **Tip** If you do not want to use fully qualified names (namespace.typename), you can use the Imports statement in Visual Basic or the using keyword in Visual C#.

The following example shows how Visual Basic and Visual C# implicitly use the namespace (and in Visual Basic, the class) qualifier:

```
' Visual Basic
' TestImports.vb
Imports System.Console
Module Module1
   Sub Main()
      WriteLine("Hello")
      ' Without the Imports statement, you would have to use
      ' System.Console.WriteLine("Hello").
      End Sub
End Module

// C#
// TestUsing.cs
using System;
```

```
class MyClass
{
   public static void Main()
   {
      Console.WriteLine("Hello");
      //  Without the using statement, you would have to use
      // System.Console.WriteLine("Hello");
   }
}
```

You can put this code into a file, called test.vb or test.cs, and compile it at the command line by typing **vbc TestImports.vb** or **csc TestUsing.cs**. You do not have to explicitly reference the mscorlib.dll, which is the assembly that contains the **System** namespace; the Visual Basic or Visual C# compiler always references mscorlib.dll.

Programming Basics Namespaces in Visual Studio

The fundamental programming namespaces in the .NET Framework include:

- System.Collections - contains interfaces and classes that define various collections of objects, such as lists, queues, arrays, hashtables, and dictionaries.
- System.IO - contains types that allow synchronous and asynchronous reading and writing on data streams and files.
- System.Text - contains classes representing ASCII, Unicode, UTF-7, and UTF-8 character encodings; abstract base classes for converting blocks of characters to and from blocks of bytes; and a helper class that manipulates and formats String objects without creating intermediate instances of **String**.
- System.Threading - provides classes and interfaces that enable multithreaded programming. This namespace includes a **ThreadPool** class that manages groups of threads, a **Timer** class that enables a delegate to be called after a specified amount of time, and a **Mutex** class for synchronizing mutually exclusive threads. **System.Threading** also provides classes for thread scheduling and wait notification.

In the Visual Studio Documentation

Walkthrough: Authoring a Simple Multithreaded Component with Visual Basic
Provides step-by-step instructions that include how to use the **System.Threading.Thread** object to add multiple threads of execution to your component.

Creating File System and Timer Components
Introduces components that respond to changes to files and directories, raise events on a schedule, or monitor and interact with Windows processes.

Walkthrough: Creating Your Own Collection Class (Visual Basic)
Provides step-by-step instructions for how to inherit from a class in **System.Collections** to create simple, strongly typed collection with Visual Basic.

C# Tutorials
Lists topics that demonstrate threading, attributes, delegates, events, and collection classes that make use of **System.Collections**; an unsafe code tutorial that covers the **System.Thread** class; and an indexers tutorial that covers **System.IO**.

Processing Drives, Folders, and Files (Visual Basic)
Lists topics that discuss using the **System.IO** namespace in Visual Basic.

Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

Working with I/O
Provides information from the *.NET Framework Developer's Guide* about I/O.

Threading
Provides information from the *.NET Framework Developer's Guide* about threading.

Data Namespaces in Visual Studio

The data and XML namespaces in the .NET Framework include:

- System.Data - consists of the classes that constitute the ADO.NET architecture, which is the primary data access method for managed applications. The ADO.NET architecture enables you to build components that efficiently manage data from multiple data sources. ADO.NET also provides the tools to request, update, and reconcile data in distributed applications.
- System.Data.Common - contains classes shared by the .NET Framework data providers. Data providers describe a collection of classes used to access a data source, such as a database, in the managed space.
- System.Xml - classes that provide standards-based support for processing XML.
- System.Data.OleDb – classes that make up the .NET Framework Data Provider for OLE DB-compatible data sources. These classes allow you to connect to an OLE DB data source, execute commands against the source, and read the results.
- System.Data.SqlClient – classes that make up the .NET Framework Data Provider for SQL Server, which allows you to connect to SQL Server 7.0, execute commands, and read results. The **System.Data.SqlClient** namespace is similar to the **System.Data.OleDb** namespace, but is optimized for access to SQL Server 7.0 and later.
- System.Data.SqlTypes - Provides classes for native data types within SQL Server. These classes provide a safer, faster alternative to other data types.
- System.Data.Odbc - classes that make up the .NET Framework Data Provider for ODBC. These classes allow you to access ODBC data source in the managed space.
- System.Data.OracleClient - classes that make up the .NET Framework Data Provider for Oracle. These classes allow you to access an Oracle data source in the managed space.

In the Visual Studio Documentation

Accessing Data
Provides conceptual and procedural information about how to work with data and XML with Visual Basic and Visual C#.
Introduction to Distributed Applications and Data Integration
Provides an overview of data access in Visual Studio applications.
Data Walkthroughs
Lists step-by-step topics covering common data scenarios.
Connecting to Data Sources with ADO.NET
Provides topics about creating and working with connection objects in Visual Studio.
ADO.NET Datasets
Provides topics about what datasets are and how to use them.
ADO.NET Data Adapters
Provides topics about defining the SQL statement or stored procedure calls that you use to fill datasets and write data back to the database.
Filtering and Sorting in Datasets
Provides topics about viewing the data in a dataset in different ways by selecting subsets of records or sorting.
Relationships in ADO.NET Datasets
Provides topics about working with dataset tables that have a parent-child relationship.
Performing Database Operations Directly
Provides topics about how to execute SQL statements and stored procedures directly and work with the results they return.
Concurrency Control in ADO.NET
Provides topics about making changes in datasets and then writing those changes back to a data source.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.
Data Access Technologies
Helps you choose a data-access technology.
XML in Visual Studio
Provides links to sections of the Visual Studio documentation that discuss XML.
Overview of Visual Database Tools
Introduces the Query Designer and other data tools.
Data Design
Provides links to Visual Studio topics about database design and data validation.

Additional Information

XML Schema Reference (XSD)

Provides reference topics for elements and data types in XML Schema, the standard developed by the World Wide Web Consortium (W3C).

Processing Transactions

Provides information from the *.NET Framework Developer's Guide* about transactions.

XML Developer Center on MSDN Online (http://msdn.microsoft.com/xml)

Provides the latest articles and other resources about XML.

World Wide Web Consortium (W3C) Web Site (http://www.w3.org/)

Provides resources about Internet standards, including XML Schema, HTML, and HTTP.

Web Namespaces in Visual Studio

The namespaces in the .NET Framework about ASP.NET Web applications and XML Web services include:

- System.Web - contains classes and interfaces that enable browser/server communication. This namespace classes for managing HTTP output to the client (**HttpResponse**) and reading HTTP requests (**HttpRequest**). Additional classes provide facilities for server-side utilities and processes, cookie manipulation, file transfer, exception information, and output cache control.
- System.Web.UI – contains classes for creating Web Form pages, including the **Page** class and other standard classes used to create Web user interfaces.
- System.Web.UI.HtmlControls – contains classes for HTML-specific controls that can be added to Web Forms to create Web user interfaces.
- System.Web.UI.WebControls – contains classes for creating ASP.NET Web sever controls. When added to a Web Form, these controls render browser-specific HTML and script to create a device-independent Web user interface.
- System.Web.Services - contains classes that enable you to build and use XML Web services, which are programmable entities residing on a Web server and exposed via standard Internet protocols.

In the Visual Studio Documentation

Introduction to ASP.NET Web Applications in Visual Studio
Provides an overview of the components of an ASP.NET Web application, including Web Forms and XML Web services, and how Visual Studio helps you create a Web application.
Creating Web Applications and Services
Provides links to all the Visual Studio topics about ASP.NET Web applications and XML Web services.
Web Forms Pages
Provides links to topics that describe what Web Forms pages are, the architecture of Web Forms pages, and how to create and work with Web Forms pages.
Programming the Web with XML Web Services
Provides information about creating and accessing XML Web services.
Working with Web Projects
Explains basic concepts about creating and managing ASP.NET Web applications, XML Web services created using ASP.NET, and Empty Web projects.
Web Walkthroughs
Lists all the step-by-step topics that incorporate Web Forms pages.
XML Web Services Walkthroughs
Lists all the step-by-step topics about creating or accessing XML Web services.
Windows Forms and Web Forms Recommendations
Discusses considerations when choosing between the two forms packages.
ASP.NET Technology Backgrounder
Provides a summary of ASP.NET technology and where Web Forms pages fit into it.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

Developing ASP.NET Server Controls
Provides information from the *.NET Framework Developer's Guide* about creating custom controls for Web Forms pages.
IBuySpy Web Site (http://www.ibuyspy.com/)
Provides sample code for ASP.NET development.
MSDN Web Site (http://msdn.microsoft.com)
Provides the latest information about XML Web services, ASP.NET, and other Microsoft technologies.

Windows Applications Namespaces in Visual Studio

The namespaces in the .NET Framework for creating rich Windows applications and graphics include:

- System.Windows.Forms - contains classes for creating Windows-based applications that take full advantage of the rich user interface features available in the Microsoft Windows operating system. In this namespace you will find the **Form** class and many other controls that can be added to forms to create user interfaces.
- System.Drawing - provides access to GDI+ basic graphics functionality. More advanced functionality is provided in the **System.Drawing.Drawing2D**, **System.Drawing.Imaging**, and **System.Drawing.Text** namespaces.
- System.ServiceProcess - provides classes that allow you to install and run long-running executables that do not have a user interface.

In the Visual Studio Documentation

Windows Forms and Web Forms Recommendations
Discusses considerations when choosing between the two forms packages.
Windows Forms
Provides links to topics about the technologies and tools for creating Windows applications.
Windows Forms Controls
Provides links to topics about the controls designed specifically to work with Windows Forms.
Windows Service Applications
Describes how to create long-running executable files.
Windows Forms Walkthroughs
Lists all the step-by-step topics that use Windows Forms in common scenarios.
Providers of Data to Windows Forms
Describes how to bind data to controls on Windows Forms and Web Forms.
GDI+ Graphics
Provides an introduction to GDI+ for Visual Basic and Visual C# users.
Color Changes in Visual Basic .NET
Provides.NET Framework **System.Drawing.Color** and **System.Drawing.SystemColors** types that are equivalent to color constants in Visual Basic 6.0.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

GDI+ SDK
Provides a comprehensive reference with C++ code examples for all aspects of GDI+ programming.
Drawing and Editing Images
Provides additional information about creating GDI+ graphics with the .NET Framework.
System.Windows.Forms Hierarchy
Provides links to all the members of the **System.Windows.Forms** namespace
System.Drawing Hierarchy
Provides links to all the members of the **System.Windows.Forms** namespace
System.ServiceProcess Hierarchy
Provides links to all the members of the **System.ServiceProcess** namespace

Component Model Namespaces in Visual Studio

The namespaces in the .NET Framework for creating your own components and controls include:

- System.ComponentModel - provides classes that are used to implement the run-time and design-time behavior of components and controls. This namespace includes the base classes and interfaces for implementing attributes, working with type converters, binding to data sources, and licensing components. The classes in this namespace divide into the following categories:
  - **Core component classes**. For more information, see Component and Container classes and IContainer and IComponent interfaces.
  - **Component licensing**. For more information, see License, LicenseManager, LicenseProvider, and LicenseProviderAttribute classes.
  - **Attributes**. For more information, see Attribute class.
  - **Descriptors and persistence**. For more information, see TypeDescriptor, EventDescriptor, and PropertyDescriptor classes.
  - **Type converters**. For more information, see TypeConverter class.
- System.CodeDOM - contains classes that can be used to represent the elements and structure of a source code document.

In the Visual Studio Documentation

Component Authoring
Provides links to all the topics about creating your own component or Windows Forms control with Visual Basic or Visual C#.
Component Programming Walkthroughs
Lists all the step-by-step topics about creating your own component or control.
Framework Services Namespaces
Provides links to reference and conceptual topics about components that interact with a variety of back-end server resources.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

Developing ASP.NET Server Controls
Provides information from the *.NET Framework Developer's Guide* about creating custom controls for Web Forms pages.
Interoperating with Unmanaged Code
Provides information from the *.NET Framework Developer's Guide* about exposing COM components to the .NET Framework and .NET Framework components to COM.
Inside the .NET Framework
Provides links to essential information about the common language runtime, assemblies, common type system, metadata, interoperability, security, and other features of the .NET Framework.

Framework Services Namespaces in Visual Studio

The namespaces in the .NET Framework for interacting with a variety of back-end server resources include:

- System.Diagnostics - consists of classes that allow you to debug your application and to trace the execution of your code. For more information, see the Trace and Debug classes. **System.Diagnostics** also provides classes that allow you to start system processes, read and write to event logs, and monitor system performance using performance counters. For more information, see the Process, EventLog, and PerformanceCounter classes.
- System.DirectoryServices - consists of classes that provide easy access to the Active Directory from managed code. The classes in this namespace can be used with any of the Active Directory service providers. The current providers are: Internet Information Services (IIS), Lightweight Directory Access Protocol (LDAP), Novell NetWare Directory Service (NDS), and Windows NT. For more information about the Active Directory, see Directory Services.
- System.IO - provides classes, including the FileSystemWatcher class, which listens to the file system change notifications and raises events when a directory, or file in a directory, changes.
- System.Management - provides classes for managing information and events about the system, devices, and applications instrumented to the Windows Management Instrumentation (WMI) infrastructure.
- System.Messaging - provides classes that allow you to connect to message queues on the network, send messages to queues, and receive or peek (read without removing) messages from queues.
- System.ServiceProcess - provides classes that allow you to install and run services. Services are long-running executables that run without a user interface. They can be installed to run under a system account that enables them to be started at computer reboot. Services whose implementation is derived from the processing in the **ServiceBase** class can define specific behavior for start, stop, pause, and continue commands, as well as behavior to take when the system shuts down.
- System.Timers - provides the server-based Timer component, which allows you to raise an event on a specified interval.

> **Note** There is also a Timer control for Windows Forms in the **System.Windows.Form** namespace and a Timer class in the **System.Threading** namespace.

In the Visual Studio Documentation

Monitoring Performance Thresholds
Provides basic information on monitoring Microsoft Windows performance thresholds.

Logging Application, Server, and Security Events
Provides additional information on monitoring Windows 2000 event logs by reading information from and writing information to them.

Creating Messaging Components
Discusses how to use the **MessageQueue** component to incorporate message-based communication into your application.

Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Monitoring and Managing Windows Processes
Provides an overview of the **Process** component and how you can use it to interact with system resources.

Tracing and Instrumenting Applications in Visual Basic and Visual C#
Provides an overview of the trace feature and how you can use it to generate output from your applications.

Creating Active Directory Components
Provides an overview on how you can use the **DirectorySearcher** and **DirectoryEntry** components to retrieve information from Active Directory file systems.

Reacting to File System Events
Provides an overview of how to use the **FileSystemWatcher** component to monitor directories for changes and react to these changes when they occur.

Monitoring Windows Services
Describes how to use the **ServiceController** component to interact with existing services.

Creating Timer-Based Server Tasks
Describes how to use the server-based **Timer** component to react to periodic events on a server.

Programming with Components
Presents a high-level overview of component programming and authoring.

Introduction to ASP.NET Web Applications in Visual Studio
Provides an overview of the components of an ASP.NET Web application, including Web Forms and XML Web services, and how Visual Studio helps you create a Web application.

Additional Information

Message Queuing (MSMQ)

Provides an entry point into the Message Queuing documentation in the Platform SDK.

Directory Services

Provides an entry point into the Active Directory documentation in the Platform SDK.

Event Logging

Provides an entry point into the Event Logging documentation in the Platform SDK.

Security Namespaces in Visual Studio

The security namespaces in the .NET Framework include:

- System.Security - provides the underlying structure of the common language runtime security system, including base classes for permissions.
- System.Web.Security - contains classes that are used to implement ASP.NET security in Web applications.

In the Visual Studio Documentation

Securing Applications Portal
Provides links to all the Visual Basic and C# topics about security.
Introduction to Web Application Security
Presents an overview of the security features provided by the ASP.NET page framework that leverage the security infrastructure supplied in the Windows operating system and Internet Information Services (IIS).
Code Security and Signing in Components
Describes how to make your application secure at installation and run time.
Message Queue Security
Gives an overview of Microsoft Windows Message Queuing.
Security Portal
Provides links to more resources.
Securability
Discusses how to provide security to an application and its data.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

.NET Framework Security
Provides information from the *.NET Framework Developer's Guide* about Web application security, code-access security, and role-based security.
Securing Applications
Provides information from the *.NET Framework Developer's Guide* about classes and services that enable developers to write secure code and enable system administrators to customize the access that code has to protected resources.
Security Best Practices
Presents Platform SDK recommendations about privileges, buffer overruns, discretionary access control lists (DACLs), and passwords.

Network Namespaces in Visual Studio

The network namespaces in the .NET Framework include:

- System.Net - contains classes that provides a simple programming interface to many of the protocols found on the network today. The **WebRequest** and **WebResponse** classes form the basis of "pluggable protocols," an implementation of network services that enables you to develop applications that use Internet resources without worrying about the specific details of the protocol used.

In the Visual Studio Documentation

Walkthrough: Creating a Distributed Application
Demonstrates the use of **System.Net** to configure Integrated Windows authentication.
Controls and Programmable Objects Compared in Different Languages and Libraries
Mentions classes in the **System.Net** namespace that replace Internet controls in earlier versions of Visual Basic.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

Best Practices for System.Net Classes
Provides recommendations for using the classes in **System.Net**.
Securing XML Web Services Created Using ASP.NET
Demonstrates the use of **System.Net** in security for XML Web services.

Configuration Namespaces in Visual Studio

The configuration namespaces in the .NET Framework include:

- System.Configuration - contains classes that are used to programmatically access .NET Framework configuration settings and handle errors in configuration files.
- System.Configuration.Assemblies - contains classes that are used to configure an assembly.
- System.Configuration.Install - provides classes that allow you to write custom installers for your own components.

In the Visual Studio Documentation

Configuring Applications Using Dynamic Properties
: Explains how you can store some of a component's property values to an external file and load them when the application runs. These dynamic properties allow you to make changes to property values, without recompiling the application, after your project has been deployed.

Introduction to the .NET Framework Class Library in Visual Studio
: Provides an overview of the namespaces in the .NET Framework.

Additional Information

Assemblies
: Provides information from the *.NET Framework Developer's Guide* about these building blocks of .NET Framework applications.

Exposing Management Data
: Demonstrates how to use **System.Configuration.Install** to create a management instrumentation instance class and publish an instance of the class to Windows Management Instrumentation (WMI).

Declaring and Accessing Custom Configuration Sections
: Demonstrates how to use **System.Configuration** to declare a custom section for your application to read at run time and retrieve settings from a configuration file.

Globalization and Localization Namespaces in Visual Studio

The namespaces in the .NET Framework for globalizing and localizing applications and components include:

- System.Globalization - contains classes that define culture-related information, including the language, the country/region, the calendars in use, the format patterns for dates, currency and numbers, and the sort order for strings.
- System.Resources - provides classes and interfaces that allow developers to create, store, and manage various culture-specific resources used in an application.
- System.Text - contains classes representing ASCII, Unicode, UTF-7, and UTF-8 character encoding.

In the Visual Studio Documentation

Introduction to International Applications in Visual Basic and Visual C#
Describes how to create an international-ready application.
Globalizing and Localizing Applications
Explains how to design and develop applications to distribute to a global audience.
Planning World-Ready Applications
Describes how to plan applications that will be distributed to an international market.
International Changes in Visual Basic .NET
Summarizes for users of Visual Basic 6.0 how locale, resources, and Unicode are handled.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

Common Resource Concepts
Provides additional information about the .NET Framework globalization and localization namespaces.

Reflection Namespaces in Visual Studio

The reflection namespace in the .NET Framework is:

- System.Reflection - contains classes and interfaces that provide a managed view of loaded types, methods, and fields, with the ability to dynamically create and invoke types.

In the Visual Studio Documentation

Providing Metadata Descriptions About Your Component
Discusses the relationship between attributes for components you create and the **System.Reflection** namespace.
Attributes Tutorial (Visual C#)
Includes a section about accessing attributes through reflection.
Introduction to the .NET Framework Class Library in Visual Studio
Provides an overview of the namespaces in the .NET Framework.

Additional Information

Reflection Overview
Provides information from the *.NET Framework Developer's Guide* about reflection and how it is commonly used.

Visual Basic Runtime Namespace in Visual Studio

The **Microsoft.VisualBasic** namespace contains modules, enumerations, and attributes that provide the properties, functions, and constants you can use in Visual Basic .NET applications. Examples of functions in this namespace include:

- **Microsoft.Visual Basic.Interaction.MsgBox**
- **Microsoft.Visual Basic.Interaction.Shell**
- **Microsoft.Visual Basic.Strings.Mid**
- **Microsoft.Visual Basic.Collection.Count**

Examples of properties and constants include **Microsoft.Visual Basic.DateAndTime.TimeOfDay** and **vbCrLf**.

Examples of attributes include **VBFixedStringAttribute**, **VBFixedArrayAttribute**, and **ComClassAttribute**.

In the Visual Basic Documentation

Visual Basic Run-Time Library Members
  Provides a complete reference for the Visual Basic run-time elements.
Namespaces
  Describes how namespaces organize objects within assemblies.
Programming Element Support Changes Summary
  Provides information on programming elements that are replaced by methods in the .NET Framework class library.
References and the Imports Statement
  Discusses how to reference and use objects in assemblies.
Attributes
  Discusses how .NET attributes provide additional information about entities defined inside a Visual Basic .NET application

Additional Information

.NET Framework Class Library in Visual Studio
  Provides an overview of the namespaces in the .NET Framework.
Introduction to the .NET Framework Class Library in Visual Studio
  Explains namespaces and assemblies.

Globalizing and Localizing Applications

If you plan on distributing your application to an international audience, there are a number of things you'll need to keep in mind during the design and development phases. Even if you don't have such plans, a small effort up front can make things considerably easier should your plans change in future versions of your application. Services built into the .NET Framework make it easy to develop a single application that can adapt to different locales using managed development with Visual Basic or Visual C#.

Visual Studio .NET was designed from the start to make developing for an international audience easy by taking advantage of services built into the .NET Framework. The following topics will help introduce you to the internationalization features built into Visual Studio .NET.

In This Section

Introduction to International Applications in Visual Basic and Visual C#
: Introduces the concepts related to developing software for an international market using Visual Basic .NET or Visual C# .NET.

Localizing Applications
: Provides links to topics about customizing applications for a given culture.

Globalizing Applications
: Provides links to topics about creating applications that support multiple cultures.

Bi-directional Language Features in Visual Studio
: Discusses the bi-directional features in Visual Studio, which support Arabic, Hebrew, Farsi, Urdu, and other languages that are written right-to-left.

Related Sections

Deployment and Localization
: Describes deployment tools in Visual Studio that allow you to distribute multiple versions of your application for different locales.

Planning World-Ready Applications
: Provides background information on programming for an international audience.

Introduction to the .NET Framework Class Library
: Introduces the classes, interfaces, and value types that expedite and optimize the development process and provide access to system functionality.

Globalization and Localization Namespaces in Visual Studio
: Lists the major namespaces for this area and provides links to .NET Framework reference topics about the types (classes, structures, enumerations, delegates, and interfaces) in the namespaces, as well as links to topics about using them in Visual Basic and Visual C# applications.

System.Globalization Namespace
: Points out the classes in this namespace, which define culture-related information, including the language, the country/region, the calendars in use, the format patterns for dates, currency and numbers, and the sort order for strings.

System.Resources Namespace
: Points out the classes and interfaces in this namespace, which allows developers to create, store, and manage various culture-specific resources used in an application.

Decision Chart
: Provides a graphical, linked guide to decisions about designing your application.

Visual Basic Code Example Topics
: Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.

Introduction to International Applications in Visual Basic and Visual C#

In Visual Studio .NET, there are two parts to creating a world-ready application: globalization, the process of designing applications that can adapt to different cultures, and localization, the process of translating resources for a specific culture. For an overview of globalization, localization, and related terminology, see Globalization and Localization Issues. For general information on designing applications for an international audience, see Planning World-Ready Applications.

The .NET localization model consists of a main assembly that contains both the application code and the fallback resources — strings, images, and other objects for the language in which the application is originally developed. Each localized application will have satellite assemblies, or assemblies which contain only the localized resources. Because the main assembly always contains the fallback resources, if a resource is not found in the localized satellite assembly, the ResourceManager will attempt to load it in a hierarchical manner, eventually falling back to the resource in the main assembly. The resource fallback system is explained in greater detail in Hierarchical Organization of Resources for Localization.

The project system for Windows Forms applications can generate resource files for both the fallback and each desired additional UI culture. The fallback resource file is built into the main assembly, and the culture-specific resource files are then built into satellite assemblies, one for each UI culture. When you build a project, the resource files are compiled from the Visual Studio XML format (.resx) to an intermediate binary format (.resources), which are then embedded in satellite assemblies.

The project system for both Windows Forms and Web Forms allows you to build resource files using an Assembly Resource File template, access the resources, and build your project. Satellite assemblies will be created along with the main assembly.

When a localized application executes, its appearance is determined by two culture values. (A *culture* is a set of user preference information related to the user's language, environment, and cultural conventions.) The UI culture setting determines which resources will be loaded. The UI culture is set as **UICulture** in Web.config files and page directives, and **CurrentUICulture** in Visual Basic or Visual C# code. The culture setting determines formatting of values such as dates, numbers, currency, and so on. The culture is set as **Culture** in Web.config files and page directives, **CurrentCulture** in Visual Basic or Visual C# code.

Walkthrough: Localizing Windows Forms

The Visual Studio project system provides considerable support for localizing Windows Forms applications. There are two ways to generate resource files using the Visual Studio development environment: one is to have the project system generate the resource files for localizable UI elements such as text and images on the form. The resource files are then built into satellite assemblies. The second way is to add a resource file template and then edit the template with the XML Designer. A reason for doing the latter is to make localizable strings that appear in dialog boxes and error messages. You must then write code to access these resources.

This walkthrough topic demonstrates both processes in a single Windows Application project.

You can also convert a text file to a resource file; for more information, see Resources in Text File Format and Resource File Generator (Resgen.exe).

To have Visual Studio generate resource files for you

1. Create a new Windows Application named "WindowsApplication1". For details see Creating a Windows Application Project.
2. In the Properties window, set the form's **Localizable** property to **true**.

   The **Language** property is already set to **(Default)**.

3. Drag a **Button** control from the Windows Forms tab of the **Toolbox** to the form, and set its **Text** property to "Hello World".
4. Set the form's **Language** property to "German (Germany)".
5. Set the button's **Text** property to "Hallo Welt".
6. Set the form's **Language** property to "French (France)".
7. Set the button's **Text** property to "Bonjour le Monde". You can resize the button to accommodate the longer string, if necessary.
8. Save and build the solution.
9. Click the "Show All Files" button in Solution Explorer.

   The resource files appear underneath Form1.vb or Form1.cs. Form1.resx is the resource file for the fallback culture, which will be built into the main assembly. Form1.de-DE.resx is the resource file for German as spoken in Germany. Form1.fr-FR.resx is the resource file for French as spoken in France.

   In addition, you will see files appear named Form1.de.resx and Form1.fr.resx. Visual Studio automatically creates these files in order to work around a limitation in Visual SourceSafe having to do with adding new files to a project during a save operation. The .resx files are empty and contain no resources.

10. Press the F5 key or choose **Start** from the **Debug** menu.

    You will now see a dialog box with an English, French, or German greeting depending on the UI language of your operating system.

    > **Note** The UI language used in Windows is a function of the CurrentUICulture setting. If your copy of Windows has a Multilingual User Interface Pack (MUI) installed, you can change UI language in the Control Panel. For more information, see the Microsoft Globalization site. If you have no MUI installed, you can change the current UI culture programmatically, as explained next.

The following procedure shows you how to set the UI culture so the application displays your French resources. In real-world applications, you would not hard-code the UI culture in this way. The setting for the UI culture would depend instead on a user setting or an application setting.

To set the UI Culture to view specific resources

1. In the Code Editor, add the following code at the beginning of the module, before the Form1 declaration:

```
' Visual Basic
Imports System.Globalization
Imports System.Threading

// C#
using System.Globalization;
using System.Threading;
```

2. Add the following code. In Visual Basic, it should go in the **New** function, before calling the **InitializeComponent** function. In Visual C#, it should go in **Form1**() and also before calling the **InitializeComponent** function.

```
' Visual Basic
' Sets the UI culture to French (France)
Thread.CurrentThread.CurrentUICulture = New CultureInfo("fr-FR")

// C#
// Sets the UI culture to French (France)
Thread.CurrentThread.CurrentUICulture = new CultureInfo("fr-FR");
```

3. Save and build the solution.
4. Press the F5 key or choose **Start** from the **Debug** menu.

   Now the form will be always displayed in French. If you changed the size of the button earlier to accommodate the longer French string, notice that the button size has also been persisted in the French resource file.

To manually add resource files to the project and edit them

1. On the **Project** menu, click **Add New Item**.
2. In the Templates box, select the **Assembly Resource File** template. Type the file name "WinFormStrings.resx" in the **Name** box. The file WinFormStrings.resx will contain fallback resources in English. These resources will be accessed whenever the application cannot find resources more appropriate to the UI culture.

   The file is added to your project in Solution Explorer and automatically opens in the XML Designer in Data view.

3. In the **Data Tables** pane, select **data**.
4. In the **Data** pane, click an empty row and enter "strMessage" in the **name** column and "Hello World" in the **value** column.

   You do not need to specify the **type** or **mimetype** for a string; they are used for objects. The type specifier holds the data type of the object being saved. The MIME type specifier holds the base type (base64) of the binary information stored, if the object consists of binary data.

5. On the **File** menu, click **Save WinFormStrings.resx**.
6. Do steps 1-5 twice more to create two more resource files named "WinFormStrings.de-DE.resx" and "WinFormStrings.fr-FR.resx", with the string resources specified in the following table. The file WinFormStrings.de-DE.resx will contain resources that are specific to German as spoken in Germany. The file WinFormStrings.fr-FR.resx will contain resources that are specific to French as spoken in France.

resource file name	name	value
WinFormStrings.de-DE.resx	strMessage	Hallo Welt
WinFormStrings.fr-FR.resx	strMessage	Bonjour le Monde

To access the manually-added resources

1. In the Code Editor, import the `System.Resources` namespace at the beginning of the code module.

```
' Visual Basic
Imports System.Resources

// C#
using System.Resources;
```

2. In Design view, double-click the button to display the code for its **Click** event handler and add the following code. The ResourceManager constructor takes two arguments. The first is the root name of the resources — that is, the name of the resource file without the culture and .resx suffixes. The second argument is the main assembly.

   In this walkthrough, no namespaces are declared, so the first argument of the **ResourceManager** constructor can take the form of "ProjectName.ResourceFileRootName". However, in a real-world application, you would set the DefaultNamespace property. In that case, you would need to declare the resource manager with the fully qualified root name of the resource file, including its namespace. For example, if the default namespace is "MyCompany.MyApplication.MyComponent", the first argument of the **ResourceManager** constructor might be "MyCompany.MyApplication.MyComponent.WinFormStrings".

```
' Visual Basic
' Declare a Resource Manager instance
Dim LocRM As New ResourceManager("WindowsApplication1.WinFormStrings", GetType(Form1).Ass
embly)
' Assign the string for the "strMessage" key to a messagebox
MessageBox.Show(LocRM.GetString("strMessage"))

// C#
// Declare a Resource Manager instance
ResourceManager LocRM = new ResourceManager("WindowsApplication1.WinFormStrings",typeof(F
orm1).Assembly);
// Assign the string for the "strMessage" key to a messagebox
MessageBox.Show(LocRM.GetString("strMessage"));
```

Note By default, the **ResourceManager** object is case-sensitive. If you wish to do case-insensitive lookups so that "TXTWELCOME" retrieves the same resource as "txtWelcome", you can set the resource manager's IgnoreCase property to **true**. However, for performance reasons, it is best to always specify the correct case for your resource names. Doing case-insensitive resource lookups can cause performance problems.

3. Build and run the form. Click the button.

   The message box will display a string appropriate for the UI culture setting; or if it cannot find a resource for the UI culture, it will display a string from the fallback resources.

Walkthrough: Localizing Web Forms Pages

When you localize Web Forms pages, the Visual Studio project system does not automatically generate resource files. You must manually create and edit the XML resource files. This walkthrough topic demonstrates how to add a resource file template and then edit the template with the XML Designer to create resources in English, German, and German as spoken in Austria. This topic also discusses how to write code to access these resources.

You can also convert a text file to a resource file. For more information, see Resources in Text File Format and Resource File Generator (Resgen.exe).

To manually create and edit a resource file

1. Create a new ASP.NET Web Application named "LocProject". For details, see Creating Web Projects.

   Note The project must be named "LocProject"; some code later in this walkthrough relies on having that name.

2. On the **Project** menu, click **Add New Item**.
3. In the Templates box, select the **Assembly Resource File** template. Type the file name "strings.resx" in the **Name** box. The file strings.resx will contain fallback resources in English. These resources will be accessed whenever the application cannot find resources more appropriate to the UI culture.

   The file is added to your project in Solution Explorer and automatically opens in the XML Designer in Data view.

4. In the **Data Tables** pane, select **data**.
5. In the **Data** pane, click an empty row and enter "txtSearch" in the **name** column and "Search for the following text:" in the **value** column.

   You do not need to specify the **type** or **mimetype** for a string; they are used for objects. The type specifier holds the data type of the object being saved. The MIME type specifier holds the base type (base64) of the binary information stored, if the object consists of binary data.

6. Click another empty row and enter "txtWelcome" in the **name** column and "Welcome to Localization!" in the **value** column.
7. On the File menu, click **Save strings.resx**.
8. Do steps 2-7 twice more to create two more resource files named "strings.de.resx" and "strings.de-AT.resx", containing the string resources specified in the following table. The file strings.de.resx will contain German resources that are neutral — that is, they apply to any region where German is spoken. The file strings.de-AT.resx will contain German resources that are specific to Austria.

resource file name	name	value
strings.de.resx	txtSearch	Nach dem folgenden Text suchen:
strings.de.resx	txtWelcome	Willkommen zur Lokalisierung!
strings.de-AT.resx	txtWelcome	Grüßt's euch zur ASP.NET Lokalisierung!

   You can enter the accented characters in a variety of ways:

   - Copying and pasting from this help topic
   - Using a German keyboard layout
   - Using the character map application charmap.exe
   - Using the Windows On-Screen Keyboard in Windows 2000 and Windows XP

   For details about using a different keyboard layout, the character map application, or the on-screen keyboard, see Windows Help.

To access the resources

1. In the Code Editor, import the `System.Resources` and `System.Globalization` namespaces at the beginning of the code module. In Visual Basic, this code should occur before the class declaration for WebForm1. In Visual C#, this code should occur before the namespace declaration. The following examples show the statements in context.

```
' Visual Basic
Imports System.Resources
Imports System.Globalization

Public Class WebForm1
```

```
   Inherits System.Web.UI.Page

// C#
using System.Resources;
using System.Globalization;

namespace LocProject
```

2. Declare a variable of type **ResourceManager** as part of the page class:

```
' Visual Basic
Public Class WebForm1
   Inherits System.Web.UI.Page
   Protected LocRM As ResourceManager

// C#
namespace LocProject_CS
{
   public class WebForm1 : System.Web.UI.Page
   {
      protected ResourceManager LocRM;
```

3. Create an instance of the **ResourceManager** class by adding the following code to the **Page_Load** method in the WebForm1 code-behind class. The ResourceManager constructor takes two arguments. The first is the root name of the resources — that is, the name of the resource file without the culture and .resx suffixes. The second argument is the main assembly.

```
' Visual Basic
LocRM = New ResourceManager("LocProject.strings", GetType(WebForm1).Assembly)

// C#
LocRM= new ResourceManager("LocProject.strings", typeof(WebForm1).Assembly);
```

Note If you did not name your project "LocProject," you should substitute the name you did use as part of the root name parameter.

To display a static resource string in the page

1. In HTML view, add some static text from a resource file with the following HTML code. Place this code between the <form> and </form> tags.

```
<h3><%=LocRM.GetString("txtWelcome")%></h3>
```

Note By default, the **ResourceManager** object is case-sensitive. If you wish to do case-insensitive lookups so that "TXTWELCOME" retrieves the same resource as "txtWelcome", you can set the resource manager's IgnoreCase property to **true**. However, for performance reasons, it is best to always specify the correct case for your resource names. Doing case-insensitive resource lookups can cause performance problems.

To assign a resource string to the property of a control

1. In Design view, drag a **Button** control from the Web Forms tab of the Toolbox to your form.
2. In the Properties window, delete the value for the button's **Text** property
3. In the Code Editor, add the following code to the **Page_Load** method to retrieve the text for the button from the resource file.

```
' Visual Basic
Button1.Text = LocRM.GetString("txtSearch")

// C#
Button1.Text = LocRM.GetString("txtSearch");
```

4. In the Code Editor, add the following code to import the `System.Threading` namespace at the beginning of the code module.

```
' Visual Basic
' Import this namespace at the beginning of the code module
Imports System.Threading

// C#
// Import this namespace at the beginning of the code module.
using System.Threading;
```

5. Add the following code to the very beginning of the **Page_Load** method to specify that the Web Forms page should display resources and formatting according to the culture specified in the browser's Accept-Language header. This code is important because otherwise your Web application will default to the culture settings of the Web server, which may not be appropriate for the remote user viewing the Web Forms page.

```
' Visual Basic
' Set the culture and UI culture to the browser's accept language
Thread.CurrentThread.CurrentCulture = CultureInfo.CreateSpecificCulture(Request.UserLangu
ages(0))
Thread.CurrentThread.CurrentUICulture = New CultureInfo(Request.UserLanguages(0))

// C#
// Set the culture and UI culture to the browser's accept language
Thread.CurrentThread.CurrentCulture = CultureInfo.CreateSpecificCulture(Request.UserLangu
ages[0]);
Thread.CurrentThread.CurrentUICulture = new CultureInfo(Request.UserLanguages[0]);
```

6. Save the project.
7. On the **Build** menu, click the **Build LocProject** command.
8. Right-click the WebForm1.aspx file in Solution Explorer and choose **View in Browser**. If you are running on a German or Austrian operating system you will see the page in German or Austrian; otherwise you will see it in English.

   If you view the page first on a system configured for German and then on a system configured for Austrian, you will notice that the Welcome text has changed to the Austrian resources, but the text for the search button has not changed. This is an example of the resource fallback system: the Austrian resources only changed the welcome text, and the remaining text defaults to the neutral German resource.

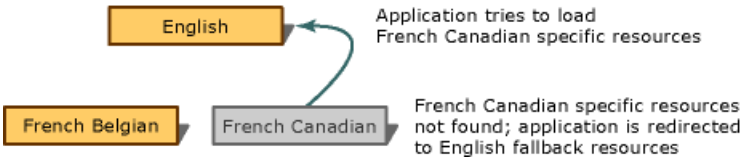
Hierarchical Organization of Resources for Localization

In Visual Studio .NET, localized resources (data such as strings and images appropriate to each culture) are stored in separate files and loaded according to the UI culture setting. To understand how localized resources are loaded, it is useful to think of them as organized in a hierarchical manner.

- At the top of the hierarchy sit the fallback resources for your default culture, for example English ("en"). These are the only resources that do not have their own file; they are stored in the main assembly.
- Below the fallback resources are the resources for any neutral cultures. A neutral culture is associated with a language but not a region. For example, French ("fr") is a neutral culture. (Note that the fallback resources are also for a neutral culture, but a special one.)
- Below those are the resources for any specific cultures. A specific culture is associated with a language and a region. For example, French Canadian ("fr-CA") is a specific culture.

If an application tries to load any localized resource, such as a string, and does not find it, it will travel up the hierarchy until it finds a resource file containing the requested resource.

The best way to store your resources is to generalize them as much as possible. That means to store localized strings, images, and so forth in resource files for neutral cultures rather than specific cultures whenever possible. For instance, if you have resources for the French Belgian ("fr-BE") culture and the resources immediately above are the fallback resources in English, a problem may result when someone uses your application on a system configured for the French Canadian culture. The system will look for a satellite assembly for "fr-CA", not find it, and load the main assembly containing the fallback resource, which is English, instead of loading the French resources. The following picture shows this undesirable scenario.



If you follow the recommended practice of placing as many resources as possible in a neutral resource file for the "fr" culture, the French Canadian user would not see resources marked for the "fr-BE" culture, but he or she would be shown strings in French. The following situation shows this preferred scenario.

Neutral Resources Languages for Localization | Security and Localized Satellite Assemblies | Localizing Applications | Globalizing and Localizing Applications | Setting the Culture and UI Culture for Windows Forms Globalization | Setting the Culture and UI Culture for Web Forms Globalization

Security and Localized Satellite Assemblies

If your main assembly uses strong naming, satellite assemblies must be signed with the same private key as the main assembly. If the public/private key pair does not match between the main and satellite assemblies, your resources will not be loaded. For information about strong names, see Strong Name Scenario. For more information on signing assemblies, see Signing an Assembly with a Strong Name.

In general, you may need to have your organization's signing group or an external signing organization sign with the private key. This is due to the sensitive nature of the private key: access is often restricted to a few individuals. You can use delayed signing during development. For more information, see Delay Signing an Assembly.

Version Numbers for Main and Localized Satellite Assemblies

The main assembly uses versioning to determine whether to load resources. The SatelliteContractVersionAttribute class provides versioning support for a main assembly. Specifying the **SatelliteContractVersionAttribute** on an application's main assembly allows you to update and re-deploy a main assembly without updating its satellite assemblies. For your localized resources to be available, the satellite contract version of your main assembly must match the AssemblyVersionAttribute class of your satellite assemblies. You must specify an exact version number in the **SatelliteContractVersionAttribute**; wildcard characters such as "*" are not allowed. For more information, see Retrieving Resources in Satellite Assemblies.

The **SatelliteContractVersionAttribute** class allows you to update a main assembly without having to update your satellite assembly, or vice versa. When the main assembly is updated, its assembly version number is changed. If you want to continue using the existing satellite assemblies, change the main assembly's version number but leave the satellite contract version number the same. For example, in your first release your main assembly version may be 1.0.0.0. The satellite contract version and the assembly version of the satellite assembly will also be 1.0.0.0. If you need to update your main assembly for a service pack, you can change the assembly version to 1.0.0.1, while keeping the satellite contract version and the satellite's assembly version as 1.0.0.0.

If you need to update a satellite assembly but not your main assembly, you change the **AssemblyVersionAttribute** of the satellite assembly. Along with your satellite assembly, you will have to ship a policy assembly that states that your new satellite assembly is compatible with your old satellite assembly. For more information on policies, see How the Runtime Locates Assemblies.

The following code shows how to set the satellite contract version. The code can be placed in either a build script or in the AssemblyInfo.vb or AssemblyInfo.cs file.

```
' Visual Basic
<Assembly: SatelliteContractVersionAttribute("4.3.2.1")>

// C#
[assembly: SatelliteContractVersionAttribute("4.3.2.1")]
```

Neutral Resources Languages for Localization

The NeutralResourcesLanguageAttribute class specifies the culture of the resources included in the main assembly. This attribute is used as a performance enhancement, so that the **ResourceManager** object does not search for resources that are included in the main assembly.

The following code shows how to set the neutral resources language. The code can be placed in either a build script or in the AssemblyInfo.vb or AssemblyInfo.cs file.

```
' Visual Basic
' Set neutral resources language for assembly.
<Assembly: NeutralResourcesLanguageAttribute("en")>

// C#
// Set neutral resources language for assembly.
[assembly: NeutralResourcesLanguageAttribute("en")]
```

Culture-Specific Classes for Global Windows Forms and Web Forms

Each culture has different conventions for displaying dates, time, numbers, currency, and other information. The System.Globalization namespace contains classes that can be used to modify how culture-specific values are displayed, such as **DateTimeFormatInfo**, **Calendar**, and **NumberFormatInfo**.

But most of the time you will use the culture setting, stored either in the application or in the **Regional Options** control panel, to automatically determine the conventions at run time and format the information accordingly. For more information on setting the culture, see Setting the Culture and UI Culture for Windows Forms Globalization or Setting the Culture and UI Culture for Web Forms Globalization. Classes that automatically format information according to the culture setting are called culture-specific. Some culture-specific methods are **IFormattable.ToString**, **Console.Writeline**, and **String.Format**. Some culture-specific functions (in the Visual Basic language) are **MonthName** and **WeekDayName**.

For example, the following code shows how you can use the **ToString** method to format currency for the current culture:

```
' Visual Basic
' Put the Imports statements at the beginning of the code module
Imports System.Threading
Imports System.Globalization
' Display a number with the culture-specific currency formatting
Dim MyInt As Integer = 100
Console.WriteLine(MyInt.ToString("C", Thread.CurrentThread.CurrentCulture))

// C#
// Put the using statements at the beginning of the code module
using System.Threading;
using System.Globalization;
// Display a number with the culture-specific currency formatting
int myInt = 100;
Console.WriteLine(myInt.ToString("C", Thread.CurrentThread.CurrentCulture));
```

If the culture is set to "fr-FR", you will see this in the output window:

```
100,00
```

If the culture is set to "en-US", you will see this in the output window:

```
$100.00
```

Setting the Culture and UI Culture for Windows Forms Globalization

The two culture values of a Visual Basic or Visual C# application determine what resources are loaded for an application and how information like currency, numbers, and dates is formatted. The resources loaded are determined by the UI culture setting, and the formatting options are determined by the culture setting. The first place an application will look for culture values is the **CurrentCulture** and **CurrentUICulture** properties. They can be set in code as shown below.

The **CurrentCulture** property's default value is the system's User Locale, which is set in the **Regional Options** control panel. The **CurrentUICulture** property's default value is the system's UI Language, which is the language of your system UI. On Windows 2000 and Windows XP MultiLanguage Edition, the **CurrentUICulture** defaults to the current user UI language settings.

In some instances, you may want to have most of your application change according to the operating system's or user's culture settings, but also have a number or date that does not change. You can have culture-specific classes format the information with the invariant culture, which is associated with the English language but no particular region. For more information on these classes, see Formatting For Different Cultures and System.Globalization Namespace. For more information on the invariant culture, see CultureInfo.InvariantCulture Property. For a list of possible culture settings, see CultureInfo Class.

To set formatting options appropriate for a specific culture

1. Set the CurrentCulture and CurrentUICulture properties if you wish to override the settings of the user or operating system. In general, you would want to specify a culture so that every part of the application's user interface is appropriate to that culture. So you must set it before the **InitializeComponent** method is called.

```
' Visual Basic
' Put the Imports statements at the beginning of the code module
Imports System.Threading
Imports System.Globalization
' Put the following code before InitializeComponent()
' Sets the culture to French (France)
Thread.CurrentThread.CurrentCulture = new CultureInfo("fr-FR")
' Sets the UI culture to French (France)
Thread.CurrentThread.CurrentUICulture = new CultureInfo("fr-FR")

// C#
// Put the using statements at the beginning of the code module
using System.Threading;
using System.Globalization;
// Put the following code before InitializeComponent()
// Sets the culture to French (France)
Thread.CurrentThread.CurrentCulture = new CultureInfo("fr-FR");
// Sets the UI culture to French (France)
Thread.CurrentThread.CurrentUICulture = new CultureInfo("fr-FR");
```

   Note The culture value must always be a specific culture (such as "fr-FR"), not a neutral culture (such as "fr"). The reason is that a neutral culture such as "fr" can apply to all French-speaking cultures, and different currencies are used in France, Belgium, and Quebec.

2. Call formatting methods with the invariant culture for any strings that should appear unchanged regardless of the **CurrentCulture** property's value.

```
' Visual Basic
Dim MyInt As Integer = 100
Dim MyString As String = MyInt.ToString("C", CultureInfo.InvariantCulture)
MessageBox.Show(MyString)

// C#
int MyInt = 100;
string MyString = MyInt.ToString("C", CultureInfo.InvariantCulture);
MessageBox.Show(MyString);
```

Encoding and Windows Forms Globalization

Windows Forms are entirely Unicode-enabled, meaning that each character is represented by a unique number, no matter what the platform, program, or language. For more information on Unicode, see the Web site of the Unicode consortium (http://www.unicode.org/).

Benefits of Unicode-enabled forms include the ability to work with scripts that are Unicode-only, such as Hindi. In addition, you can use multiple languages on a single form. In Unicode, all characters are two bytes long, so no special effort is needed to represent double-byte characters. You can also write a single set of code which will work on all platforms. This is a change from previous versions of Visual Basic, in which you had to write different code for different platforms such as Windows NT and Windows 98.

However, certain controls do not support Unicode in Windows 98 and Windows Millennium Edition. These controls, all of which inherit from the common control, will process data with the Windows code pages, as ANSI. These controls are: **TabControl**, **ListView**, **TreeView**, **DateTimePicker**, **MonthCalendar**, **TrackBar**, **ProgressBar**, **ImageList**, **ToolBar**, and **StatusBar**. The result of this is that you cannot display Unicode data in these controls on the listed platforms. For example, you cannot display Japanese characters on an English Windows 98 system.

Globalizing Windows Forms | Globalizing and Localizing Applications

International Fonts in Windows Forms and Controls

The recommended method of selecting fonts is to use font fallback wherever possible. Font fallback means that the system determines what script the character belongs to. To take advantage of this feature, do not set the **Font** property for your form or any other element. The application will automatically use the default system font, which differs from one localized language of the operating system to another. When the application runs, the system will automatically provide the correct font for the culture selected in the operating system.

There is an exception to the rule of not setting the font, which is for changing the font style. This might be important for an application in which the user clicks a button to make text in a text box appear in boldface. To do that, you would write a function to change the text box's font style to bold, based on whatever the form's font is. It is important to call this function in two places: in the button's **Click** event handler and in the **FontChanged** event handler. If the function is called only in the **Click** event handler and some other piece of code changes the font family of the entire form, the text box will not change with the rest of the form.

```
' Visual Basic
Private Sub MakeBold()
   ' Change the TextBox to a bold version of the form font
   TextBox1.Font = New Font(Me.Font, FontStyle.Bold)
End Sub

Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As System.EventArgs) Handles
Button1.Click
   ' Clicking this button makes the TextBox bold
   MakeBold()
End Sub

Private Sub Form1_FontChanged(ByVal sender As Object, ByVal e As System.EventArgs) Handles My
Base.FontChanged
   ' If the TextBox is already bold and the form's font changes,
   ' change the TextBox to a bold version of the new form font
   If (TextBox1.Font.Style = FontStyle.Bold) Then
      MakeBold()
   End If
End Sub

// C#
private void button1_Click(object sender, System.EventArgs e)
{
   // Clicking this button makes the TextBox bold
   MakeBold();
}

private void MakeBold()
{
   // Change the TextBox to a bold version of the form's font
   textBox1.Font = new Font(this.Font, FontStyle.Bold);
}

private void Form1_FontChanged(object sender, System.EventArgs e)
{
   // If the TextBox is already bold and the form's font changes,
   // change the TextBox to a bold version of the new form font
   if (textBox1.Font.Style == FontStyle.Bold)
   {
      MakeBold();
   }
}
```

However, when you localize your application, the bold font may display poorly for certain languages. If this is a concern, you want the localizers to have the option of switching the font from bold to regular text. Since localizers are typically not developers and do not have access to source code, only to resource files, this option needs to be set in the resource files. To do this, you would set the **Font.Bold** property to **true**. This results in the font setting being written out to the resource files, where localizers can edit it. You then write code after the **InitializeComponent** method to reset the font based on whatever the form's font is, but using the font style specified in the resource file.

```
' Visual Basic
TextBox1.Font = New System.Drawing.Font(Me.Font, TextBox1.Font.Style)

// C#
textBox1.Font = new System.Drawing.Font(this.Font, textBox1.Font.Style);
```

Displaying Right-to-Left Text in Windows Forms for Globalization

Certain scripts, such as Arabic, are written from right to left. When you display these scripts, not only must the script flow in the reverse direction from the English language, but also visual alignment of form elements must be reversed. In this version, when you set a form's or control's **RightToLeft** property to **RightToLeft.Yes**, the left or right alignment is reversed for elements such as check boxes, vertical scroll bars on scrollable controls, and text in the title bars of forms. For a list of these effects, see Control.RightToLeft Property.

You do not need to change the values of properties such as the **TextAlign** value of a **TextBox** control: the value stays the same but the alignment is reversed.

To display right-to-left text

- Set the form's **RightToLeft** property to **RightToLeft.Yes**.

  All controls on the form will inherit the right-to-left setting, since the default value for the **RightToLeft** property of the **Control** class is **RightToLeft.Inherit**.

- If you wish to override the setting for a particular control, set that control's **RightToLeft** property to **RightToLeft.No**.

Control.RightToLeft Property | MainMenu.RightToLeft Property | ContextMenu.RightToLeft Property | RightToLeft Enumeration | Globalizing Windows Forms | Globalizing and Localizing Applications

Display of Asian Characters with the ImeMode Property

The **ImeMode** property is used by forms and controls to force a specific mode for an input method editor (IME). The IME is an essential component for writing Chinese, Japanese, and Korean scripts, since these writing systems have more characters than can be encoded for a regular keyboard. For example, you may want to allow only ASCII characters in a particular text box. In such a case you can set the **ImeMode** property to **Disable** and users will only be able to enter ASCII characters for that particular text box. The default value of the **ImeMode** property is **ImeMode.Inherit**, so if you set the property for a form, all controls on the form will inherit that setting. For more information, see Control.ImeMode Property and ImeMode Enumeration.

Bi-directional Language Features in Visual Studio
Discusses the bi-directional features in Visual Studio, which support Arabic, Hebrew, Farsi, Urdu, and other languages that are written right-to-left.

Setting the Culture and UI Culture for Web Forms Globalization

By specifying a culture it is possible to use a set of common preferences for information like strings and date and number formats that correspond to users' cultural conventions. A Web Forms page has two culture values, **Culture** and **UICulture**. The **Culture** value determines or influences results of culture-dependent functions, such as displaying the date. The **UICulture** value determines how the resources are loaded for the form and is used for culture-specific lookup of resource data. The only purpose of the **UICulture** value is to indicate the language the resources should load, that is, determine which language the UI strings should use. The **Culture** value determines everything else — date formatting, number formatting, and so on.

The two culture settings do not need to have the same value. Depending on your application, it may be important to set them separately. An example is a Web auction site. The UI culture changes for each Web browser, but the culture stays constant, so prices are always displayed in the same currency and formatting.

The **Culture** value can only be set to specific cultures such as en-US or en-GB. This prevents the problem of identifying the correct currency symbol to use for "en", where en-US and en-GB have different currency symbols.

To set the Culture and UI Culture values

- In the Globalization section of the Web.config file, add lines similar to the code below. For more information on Web.config files, see Editing the Web.config File for Web Forms Globalization.

  ```
  culture="en-US"
  uiCulture="de"
  ```

  -or-

- In HTML view, add the **Culture** and **UICulture** values to the page directive.

  ```
  <%@ Page UICulture="de" Culture="en-US"...%>
  ```

  -or-

- In the Code Editor, add code to set the **CurrentCulture** and **CurrentUICulture** properties.

  The following example sets both the **CurrentCulture** and the **CurrentUICulture** properties to the culture specified in the browser's Accept-Language header. Note that the **CurrentCulture** property is set using the **CreateSpecificCulture** method, since this property must be set to a specific culture and not a neutral culture.

  ```
  ' Visual Basic
  ' Import these namespaces at the beginning of the code module
  Imports System.Globalization
  Imports System.Threading

  ' Set the culture and UI culture to the browser's accept language
  Thread.CurrentThread.CurrentCulture = CultureInfo.CreateSpecificCulture(Request.UserLangu
  ages(0))
  Thread.CurrentThread.CurrentUICulture = New CultureInfo(Request.UserLanguages(0))

  // C#
  // Import these namespaces at the beginning of the code module.
  using System.Globalization;
  using System.Threading;

  // Set the culture and UI culture to the browser's accept language
  Thread.CurrentThread.CurrentCulture = CultureInfo.CreateSpecificCulture(Request.UserLangu
  ages[0]);
  Thread.CurrentThread.CurrentUICulture = new CultureInfo(Request.UserLanguages[0]);
  ```

Globalizing Web Forms Pages | @ Page

Selecting an Encoding for Web Forms Globalization

Internally, the code behind Web Forms pages handles all string data as Unicode. You can set the **ResponseEncoding** attribute to set the encoding that the server uses to send data to the client, for example UTF-8. The Web Forms page also sets the **CharSet** attribute on the **Content-Type** of the HTTP header according to the value of **ResponseEncoding**. This enables browsers to determine the encoding without a meta tag or having to guess the correct encoding from the content.

The **RequestEncoding** attribute indicates the encoding the server will use to interpret data entered on the client and sent to the server. The **FileEncoding** attribute specifies the encoding that is used to interpret the data included in the aspx file. If the file encoding is specified in the Web.config file, the actual file must be saved in the same encoding. To select an encoding different from the system default, use the Advanced Save Options dialog box (available on the File menu).

> **Note** The name of your Web project may not display correctly on a remote user's system if the name of your Web project uses a double-byte character set (DBCS) that is not the language of the remote user's operating system. If you are using FrontPage server extensions, the project name must also match the language of the Web server's operating system in order to display correctly.

To specify encoding

- Set the appropriate encoding in the Web.config file. For more information on Web.config files, see Editing the Web.config File for Web Forms Globalization.

  -or-

- In HTML view, add the encoding values to the page directive.

```
<%@ Page ResponseEncoding="utf-8" RequestEncoding="utf-8"%>
```

> **Note** You can use the **Page** directive to specify any attribute except for **fileEncoding**, because it applies to the file itself. You can use the **globalization** section of the Web.config file to specify any attribute, including **fileEncoding**.

See Also

Globalizing Web Forms Pages

Editing the Web.config File for Web Forms Globalization

Web Forms configuration files, named Web.config, provide settings for every Web Forms page in the same directory as the configuration file. The settings are usually also inherited by subdirectories. Each file can contain a **globalization** section in which you can specify default encodings and cultures. Values are valid if they are accepted by the related Encoding and CultureInfo classes. For more information on the contents of the Globalization section, see <globalization> Element. For general information on Web.config files, see ASP.NET Configuration.

The Web.config file is case-sensitive, so specifying a value for "FileEncoding" will not have the desired effect, but specifying a value for "fileEncoding" will. For more information, see Format of ASP.NET Configuration Files.

To edit the Web.config file

- Set the values of **fileEncoding**, **requestEncoding** and **responseEncoding** to specify the way in which .aspx files, request data and response data are encoded. For more information on encoding values, see Selecting an Encoding for Web Forms Globalization

  If the file encoding is specified in the Web.config file, the actual file must be saved in the same encoding. To select an encoding different from the system default, use the Advanced Save Options dialog box (available on the File menu).

- Set the values of **culture** and **uiCulture**. For more information on culture values, see Setting the Culture and UI Culture for Web Forms Globalization.

```
<configuration>
   <system.web>
      <globalization
           fileEncoding="utf-8"
           requestEncoding="utf-8"
           responseEncoding="utf-8"
           culture="en-US"
           uiCulture="de-DE"
        />
   </system.web>
</configuration>
```

Note The attributes of the **globalization** section in the Web.config file can also be specified in the @ Page directive (with the exception of **fileEncoding**, which can only be specified in Web.config because it applies to the file itself). Settings in the Page directive are only valid for a specific page and override the settings of the Web.config file.

Globalizing Web Forms Pages

Displaying Right-to-Left Text Using HTML Tags for Globalization

When writing Web Forms pages, the best way to make text flow from right to left is to use the DIR (direction) attribute. It is usually placed in the <HTML> tag or the <BODY> tag, and then controls and HTML elements on the page inherit the specified direction.

Which tag the DIR attribute is applied to affects how the form appears:

- When direction is specified as RTL (right-to-left) in the <HTML> tag, the page will get the correct extended styles set so it displays as a right-to-left page on a bidirectional-enabled system and a vertical scrollbar appears on the left side.
- When direction is specified as RTL in the <BODY> tag, frames and captions will not inherit the right-to-left direction.

There are other ways to set the flow of text, including the <BDO> tag for bidirectional override, Unicode characters which have embedded directional information, and cascading style sheets. For more information, see Authoring HTML for Middle Eastern Content on the Global Software Development site on Microsoft.com (http://www.microsoft.com/globaldev/articles/mideast.asp).

To set the direction attribute in a Web Forms page

1. In Design view, select the document. In the Properties window, set the **dir** property to `ltr` or `rtl`.

   -or-

   In HTML view, edit the <HTML> or <BODY> tag to add the DIR attribute.

   ```
   <HTML dir="rtl">
   <!-- Or -->
   <body dir="rtl" >
   ```

2. In Design view, select any HTML server controls for which you wish to override the DIR attribute of the rest of the document. In the Properties window, set the **dir** property of those controls to `ltr` or `rtl`.

   -or-

   In HTML view, edit the tags of any HTML elements, HTML server controls, or Web Forms controls for which you wish to override the DIR attribute.

   ```
   <TABLE dir="ltr" >
   <asp:TextBox dir="ltr" >
   ```

HTML Layout Guidelines for Web Forms Globalization

The best practice for HTML layout is to ensure that localizers only need to translate strings, since the user interface will automatically size all controls to fit. The step of resizing is removed from the localization process, thereby removing the errors and bugs that usually result. The following are recommendations for designing Web Forms for globalization.

- **Never use Cascading StyleSheet (CSS) properties for absolute positions.** Specifying absolute positions prevents elements from being automatically positioned and sized.

```
<!-- Do not do this -->
<DIV id = idFindWhatLabel style = "position: absolute; left: 0.98em; top: 1.2168em; width
: 4.8em; height: 1.2168em;">
```

- **Forms should take advantage of the available width and height.** There are two ways to do this. First, size major elements such as tables to width=100%. Second, size elements using CSS expressions based on the overall size of the form.

```
<!-- Table sized to take up entire width of the form-->
  <table width=100%>

<!-- div sized to take up half the width and height of the form -->
<div style='position:absolute; left: 0; top: 0;
  height: expression(document.body.clientHeight / 2);
  width: expression(document.body.clientWidth / 2); '>
```

- **Each control should be in a separate table cell.** This allows text to wrap independently and ensures correct alignment for cultures in which text layout flows from right to left.
- **Allow wrapping text.** Avoid the "nowrap" attribute for table cells that contain text. Only use this attribute when you want the text to stay on one line and there is enough room for the text to expand to accommodate any language.
- **Separate check boxes and radio buttons from their label text.** Place the labels for check boxes and radio buttons in separate cells from the controls. This allows the text to wrap correctly when the text grows longer. However, you should still design the form so that the text has a reasonable chance of staying on one line when it is translated.
- **Leave room for growth, and avoid fixed widths.** Text may expand when translated into other languages. A good rule of thumb is to leave room for 300% growth on short strings (fewer than 10 characters), 200% growth on medium strings (10-20 characters), and 100% growth on large strings (more than 20 characters).

  One acceptable solution is to set table cell width to a percentage of the form width so the cell can expand relative to the entire table. However, try to specify as few relative sizes (other than 100%) as possible, because you want the HTML layout engine to do most of the work for you.

```
<!-- Table cell sized to take up one quarter width of the table -->
 <td width=25%>
```

- **Size buttons in as few places as possible.** Often there is a set of buttons that should have the same size. Set this size in one place for the entire set of buttons, if possible. Allow room for the text to expand in list boxes and group boxes.
- **Set height as seldom as possible.** Do not set the cell height for any table cell or control that contains text. (You may set the line height for CSS elements.) Otherwise, the look of the page will change if the user sets the text size in the browser.
- **Do not use left or right align in HTML tags.** In general, avoid setting "align=left" or "align=right" for any table cell. These properties may interfere with the layout of forms for cultures in which text layout flows from right to left.
- **Avoid inline CSS values that may need to be changed.** Keep all CSS values that localizers may need to change in style sheets, rather than inline. This includes setting the font for a page.

Visual Studio .NET With Arabic Language Support
This whitepaper on the Microsoft.com Web site provides details on support for Arabic in applications created with Visual Studio. It includes Arabic-specific information about text formatting, calendar support, Windows Forms and controls, Web Forms, culture-specific classes in the .NET Framework, and Crystal Reports.

Bi-directional Features at Design Time in Visual Studio

Visual Studio allows you to work with bi-directional languages as you create applications. Visual Studio itself is not fully bi-directional, but it does allow you to create fully bi-directional applications.

> **Note** In order to enter and display bi-directional languages, you must be working with a version of Windows that is configured with the appropriate language. This can either be an English version of Windows with the appropriate language pack installed, or the appropriately localized version of Windows.

Features That Are Fully Supported

At design time in Visual Studio, you can use bi-directional languages in these ways:

- **Text entry** Visual Studio supports Unicode, so if your system is set to the appropriate locale and input language, you can enter text in Arabic or Hebrew. (Arabic support includes Kashida and Diacritics.)
- **Object names** You can use bi-directional languages to assign names to solutions, projects, files, folders, and so on. In code, you can use bi-directional languages for the names of variables, classes, object, attributes, metadata, and other elements. For details, see Arabic or Hebrew Text in Object Names.
- **File encoding** You can save and open files with a language-specific or Unicode encoding. For details, see Saving and Opening Files with Encoding.

Features with Limited or No Support

Other features common to bi-directional language applications are not fully supported in Visual Studio, or in some cases, not at all. These include:

- **Right-to-left reading order** By default, text-entry controls you use in Visual Studio use left-to-right reading order. In most cases, you can use standard Windows gestures to switch reading order. For example, you can press Ctrl+Right Shift to switch the Properties window to support right-to-left reading order for property values.

  However, right-to-left reading order is not supported everywhere in Visual Studio. Exceptions include:

  - Check boxes, drop-down lists, and other controls in Visual Studio dialog boxes always use left-to-right reading order.
  - The code editor (and text editor) does not support right-to-left reading order. You can enter text in a bi-directional language, but the reading order is always left-to-right.

See Also

Arabic or Hebrew Text in Object Names | Saving and Opening Files with Encoding | Globalizing and Localizing Applications | Visual Studio .NET With Arabic Language Support (this link goes to the Microsoft.com Web site)

Arabic or Hebrew Text in Object Names

You can use Arabic or Hebrew text to assign names to folders, variables, or other objects. When working with Arabic, you can use any Arabic characters including Kashida and Diacritics.

> **Note** Your Windows system and user locales must be set to the appropriate language in order to be able to enter Arabic or Hebrew into the dialog boxes displayed during installation.

The following elements can be named using Arabic or Hebrew and will be handled correctly in Visual Studio:

- Solution, project, and file names, including any folders you include in the project path. Solution Explorer will display solution and element names correctly.
- File contents. You can open or save files with Unicode encoding or with a selected code page.

  > **Note** The code editor is a special case. For details, see below.

- Data elements. Server Explorer will display these elements correctly and allow you to edit them.
- Elements copied to the Windows Clipboard.
- Attributes and metadata.
- Property values. You can use Arabic or Hebrew text in the Properties window. The window allows you to switch between right-to-left and left-to-right reading order using standard Windows keystrokes (Ctrl+RightShift for right-to-left, and Ctrl+LeftShift for left-to-right).
- Code and literal text. In the code editor (which is also the text editor), you can use Arabic or Hebrew to name classes, functions, variables, properties, string literals, attributes, and so on. However, the editor does not support right-to-left reading order; text always starts at the left margin.

  > **Tip** It is recommended that you place string literals in resource files instead of hard-coding them into your programs. For details, see Walkthrough: Localizing Windows Forms.

  > **Note** You must be consistent in how you refer to objects named in these languages. For example, if you use Kashida in naming an Arabic variable, you must always use Kashida when referring to that variable, or errors will result.

- Code comments. You can create comments in Arabic or Hebrew. You can also use these languages in the comment builder tool.

Bi-Directional Features at Design Time in Visual Studio | Saving and Opening Files with Encoding | Globalizing and Localizing Applications | Visual Studio .NET With Arabic Language Support (this link goes to the Microsoft.com Web site)

Saving and Opening Files with Encoding

You can save files with specific character encoding to support bi-directional languages. You can also specify an encoding when opening a file, so that Visual Studio displays the file correctly.

To save a file with encoding

1. From the File menu, choose **Save File As**, and then click the drop-down button next to the **Save** button.

   The **Advanced Save Options** dialog box is displayed.

2. Under **Encoding**, select the encoding to use for the file.
3. Optionally, under **Line endings**, select the format for end-of-line characters.

   This option is useful if you intend to exchange the file with users of a different operating system.

If you want to work with a file that you know is encoded in a specific way, you can tell Visual Studio to use that encoding when opening the file. The method you use depends on whether the file is part of your project.

To open an encoded file that is part of a project

1. In Solution Explorer, right-click the file and choose **Open With**.
2. In the **Open With** dialog box, choose the editor to open the file with.

   Many Visual Studio editors, such as the forms editor, will auto-detect the encoding and open the file appropriately. If you choose an editor that allows you to choose an encoding, the **Encoding** dialog box is displayed.

3. In the **Encoding** dialog box, select the encoding that the editor should use.

To open an encoded file that is not part of a project

1. On the **File** menu, point to **Open**, choose **File** or **File From Web**, and then select the file to open.
2. Click the drop-down button next to the **Open** button and choose **Open With**.
3. Follow Steps 2 and 3 from the preceding procedure.

Encoding and Windows Forms Globalization | Bi-Directional Features at Design Time in Visual Studio | Arabic or Hebrew Text in Object Names | Globalizing and Localizing Applications

Creating Applications for Bi-directional Languages with Visual Studio

You can use Visual Studio to create applications that correctly display text in languages written right-to-left, including Arabic and Hebrew. For some features, you can simply set properties. In other cases, you must implement features in code.

> **Note** In order to enter and display bi-directional languages, you must be working with a version of Windows that is configured with the appropriate language. This can either be an English version of Windows with the appropriate language pack installed, or the appropriately localized version of Windows.

Windows Applications

You can create fully bi-directional applications that include support for bi-directional text, right-to-left reading order, and mirroring (reversing the layout of windows, menus, dialog boxes, and so on). Except for mirroring, these features are available by default or as property settings. Mirroring is supported inherently for some features, such as message boxes. However, in other cases you must implement mirroring in code.

For details, see Bi-directional Support for Windows Applications.

Web Applications

Web applications rely on browsers for their user interface, so the degree of bi-directional support in a Web application is somewhat dependent on how well the user's browser supports those bi-directional features. In Visual Studio, you can create applications with support for Arabic or Hebrew text, right-to-left reading order, file encoding, and local culture settings.

Web services likewise support and receiving sending UTF-8 and Unicode text, making them suitable for applications involving bi-directional languages.

For details, see Bi-directional Support for Web Applications.

Console Applications

Console applications do not include text support for bi-directional languages. This is not directly a limitation of Visual Studio; it is a consequence of how Windows works with console applications.

See Also

Bi-directional Support for Windows Applications | Bi-directional Support for Web Applications | Globalizing Windows Forms | Localizing Applications

Bi-directional Support for Windows Applications

You can use Visual Studio to create Windows applications that support bi-directional languages such as Arabic and Hebrew. This includes standard forms, dialog boxes, MDI forms, and all the controls you can work with in these forms — that is, all the objects in the System.Windows.Forms.Control namespace.

Culture Support

Culture and UI culture settings determine how an application works with dates, times, currency, and other information. Support for culture and UI culture is the same for bi-directional languages as it is for any other languages. For details, see Culture-Specific Classes for Global Windows Forms and Web Forms.

RightToLeft Property

The base **Control** class (from which forms derive) includes a RightToLeft property that you can set to change the reading order of a form and its controls. If you set the form's **RightToLeft** property, by default controls on the form inherit this setting. However, you can also set the **RightToLeft** property individually on most controls. For details, see Displaying Right-to-Left Text in Windows Forms for Globalization.

The effect of the **RightToLeft** property can differ from one control to another. In some controls it only sets the reading order, as in the **Button**, **TreeView** and **ToolTip** controls. In other controls, the **RightToLeft** property changes both reading order and layout. This includes the **RadioButton**, **ComboBox** and **CheckBox** controls. The following table provides details on how the **RightToLeft** property affects individual Windows Forms controls.

Control/Component	Effect of RightToLeft property	Requires mirroring?
Button	Sets the RTL reading order	No
CheckBox	The check box is displayed on the right side of the text	No
CheckedListBox	All the check boxes are displayed on the right side of the text	No
ColorDialog	Not affected; depends on the language of the operating system	No
ComboBox	Items in combo box control are right-aligned	No
ContextMenu	Appears right-aligned with RTL reading order	No
DataGrid	Appears right-aligned with RTL reading order	No
DateTimePicker	Not affected; depends on the language of the operating system	No
DomainUpDown	Left-aligns the up and down buttons	No
ErrorProvider	Not supported	No
FontDialog	Depends on the language of the operating system	No
GroupBox	The caption is displayed right aligned. Child controls may inherit this property.	No
HScrollBar	Starts with the scroll box (thumb) right-aligned	No
ImageList	Not required	No
Label	Displayed right-aligned	No
LinkLabel	Displayed right-aligned	No
ListBox	Items are right-aligned	No
ListView	Sets the reading order to RTL; elements stay left-aligned	Yes
MainMenu	Displayed right-aligned with RTL reading order at run time (not at design time)	No
MonthCalendar	Not affected; depends on the language of the operating system	No
NotifyIcon	Not supported	No
NumericUpDown	Up and down buttons are left-aligned	No
OpenFileDialog	Not affected; depends on the language of the operating system	No
PageSetupDialog	Not affected; depends on the language of the operating system	No
Panel	Child controls may inherit this property	Yes
PictureBox	Not supported	No
PrintDialog	Not affected; depends on the language of the operating system	No
PrintDocument	The vertical scroll bar become left-aligned and the horizontal scroll bar starts from the left	No
PrintPreview	Not affect by this property	No
PrintPreviewDialog	Text displayed in a form's title bar is right-aligned	No

ProgressBar	Not affect by this property	Yes
RadioButton	The radio button is displayed on the right side of the text	No
RichTextBox	Control elements that include text are displayed from right to left with RTL reading order	No
SaveFileDialog	Not affected; depends on the language of the operating system	No
Splitter	Not supported	No
StatusBar	The text in the panels is right-aligned with RTL reading order	Yes
TabControl	Not affected by this property	Yes
TextBox	Displays text from right to left with RTL reading order	No
Timer	Not required	No
ToolBar	Not affected by this property	Yes
ToolTip	Sets the RTL reading order	No
TrackBar	The scroll or track starts from the right	No
TreeView	Sets the RTL reading order only	Yes
VScrollBar	Displayed on the left side rather than right side of scrollable controls	No

Encoding

Windows Forms support Unicode, so you can include any character set when creating them. However, not all Windows Forms controls support Unicode on all platforms. For details, see Encoding and Windows Forms Globalization.

GDI+

You can use GDI+ to draw text with right-to-left reading order. The DrawString method, which is used to draw text, supports a **StringFormat** parameter that you can set to the **DirectionRightToLeft** member of the StringFormatFlags enumeration in order to reverse the point of origin for the text.

Common Dialog Boxes

System tools such as the File Open dialog box are under the control of Windows. They inherit language elements from the operating system. If you are using a version of Windows with the correct language settings, these dialog boxes will work properly with bi-directional languages.

Similarly, message boxes go through the operating system and support bi-directional text. The captions on message box buttons are based on the current language setting. By default, message boxes do not use right-to-left reading order, but you can specify a parameter to change this when displaying the message box. For details, see
Creating Message Boxes for Bi-Directional Windows Applications.

Mirroring

Mirroring refers to reversing the layout of UI elements so that they flow from right to left. In a mirrored Windows Form, for example, the Minimize, Maximize, and Close buttons appear left-most on the title bar, not right-most.

Setting a form or control's **RightToLeft** property to **true** reverses the reading order of elements on a form, but it does not reverse the layout to be right-to-left — that is, it does not cause mirroring. For example, it does not move the Minimize, Maximize, and Close buttons in the form's title bar to the left side of the form. Similarly, some controls, such as the **TreeView** control, require mirroring in order to change their display to be appropriate for Arabic or Hebrew.

You cannot directly mirror a form or control. However, you can create mirroring in code. For forms, you can set an extended Window style to cause mirroring. For most controls that require mirroring, you can create a mirrored control by inheriting from the base control and setting the same Windows extended style. For details, see Creating Mirrored Windows Forms and Controls.

You can create mirrored versions of the following controls.

ListView	**Panel**	**StatusBar**
TabControl	**TabPage**	**ToolBar**
Treeview		

Some controls are sealed, so you cannot derive a new control from them. These include the **ImageList** and **ProgressBar** controls.

Bi-directional Support for Web Applications | Globalizing Windows Forms | Localizing Applications | Visual Studio .NET With Arabic Language Support (this link goes to the Microsoft.com Web site)

Creating Mirrored Windows Forms and Controls

Windows Forms do not directly support mirroring. However, the Windows operating system itself does. You can therefore create a mirrored form in Visual Studio and set a Windows-defined extended style so that a Windows Form displayed in a mirrored fashion.

To create a mirrored Windows Form or control

1. Create a new class for the form or control:
   - If you are creating a mirrored form, the class should derive from System.Windows.Forms.Form.
   - If you are creating a mirrored control, the class should derive from the control you want to mirror, such as System.Windows.Forms.TreeView or System.Windows.Forms.Panel.
2. Override the base class's CreateParams property. Because this is a read-only property, you only need to create the property's get method.
3. In the overridden property, create an instance of the System.Windows.Forms.CreateParams class and set its ExStyle property.

   The **ExStyle** property is a bit field in which specific bits control various style attributes of the window.
4. Using bit-wise OR operators, set the following bits in the **CreateParams** object's **ExStyle** property to **true**:
   - x400000 (WS_EX_LAYOUTRTL) This bit setting specifies that the form or control will have a right-to-left layout (hence, will be mirrored). Set this for both forms and controls.
   - x100000 (WS_EX_NOINHERITLAYOUT) This setting specifies that the form or control's layout is not inherited by child controls.
   - Mirroring for child controls of the mirrored form should be set using their RTL property or by other means.

   Tip The constants used for the bit-wise settings are a Windows convention, defined in the winuser.h file.

The following example illustrates how to create a Windows form that is mirrored.

```
' Visual Basic
Public Class MirroredForm
    Inherits System.Windows.Forms.Form
    Const WS_EX_LAYOUTRTL = &H400000
    Const WS_EX_NOINHERITLAYOUT = &H100000
    Protected Overrides ReadOnly Property CreateParams() _
        As System.Windows.Forms.CreateParams
        Get
            Dim CP As System.Windows.Forms.CreateParams = _
                MyBase.CreateParams
            If Not MyBase.DesignMode() Then
               CP.ExStyle = CP.ExStyle Or WS_EX_LAYOUTRTL Or _
                   WS_EX_NOINHERITLAYOUT
            End If
            Return CP
        End Get
    End Property
    ' Rest of Form code here
End Class

// C#
const int WS_EX_LAYOUTRTL = 0x400000;
const int WS_EX_NOINHERITLAYOUT = 0x100000;
protected override CreateParams CreateParams
{
    get
    {
        CreateParams CP = base.CreateParams;
        if (! base.DesignMode)
            CP.ExStyle = CP.ExStyle | WS_EX_LAYOUTRTL
                | WS_EX_NOINHERITLAYOUT;
        return CP;
```

```
    }
}
// Rest of form code here
```

In some situations, it is useful to create a property that allows you to turn mirroring on or off.

To create a property to control mirroring

1. Create a Boolean property to control mirroring. For details about creating properties, see Property Procedures (Visual Basic .NET) or Properties Tutorial (Visual C# .NET).
2. Optionally, include attributes that allow you to expose the property at design time. If you want to include attributes, you must also import the System.ComponentModel namespace. For details, see Attributes Overview.
3. In the property's set method, call the base class's OnRightToLeftChanged method so that derived classes are notified of the change to the property.
4. Override the base class's CreateParams property as described in the previous procedure. In the overridden property, set the extended Windows style if mirroring is true.

   The following example shows the relevant code from a mirrored TreeView control that implements a property called `mirrored`. The example includes some design-time attributes so that the `mirrored` property can be exposed in the Properties window.

```
' Visual Basic
Imports System.ComponentModel
Public Class MirroredTreeView
    Inherits System.Windows.Forms.TreeView
    Private _mirrored As Boolean = False
    <Description("Change to the right-to-left layout."), _
    DefaultValue(False), Localizable(True), _
    Category("Appearance"), Browsable(True)> _
    Public Property Mirrored() As Boolean
        Get
            Return _mirrored
        End Get
        Set(ByVal Value As Boolean)
            If _mirrored <> Value Then
                _mirrored = Value
                MyBase.OnRightToLeftChanged(EventArgs.Empty)
            End If
        End Set
    End Property

    Protected Overrides ReadOnly Property CreateParams() _
        As System.Windows.Forms.CreateParams
        Get
            Dim CP As System.Windows.Forms.CreateParams = _
                MyBase.CreateParams
            If Mirrored Then
                CP.ExStyle = CP.ExStyle Or &H400000
            End If
            Return CP
        End Get
    End Property

    ' Rest of control code here

End Class

// C#
public class MirroredTreeView : System.Windows.Forms.TreeView
{
```

```
    const int WS_EX_LAYOUTRTL = 0x400000;
    private bool _mirrored= false;
    [Description("Change to the right-to-left
       layout."),DefaultValue(false),
        Localizable(true),Category("Appearance"),Browsable(true)]
    public bool Mirrored
    {
        get
        {
            return _mirrored;
        }
        set
        {
            if (_mirrored != value)
            {
                _mirrored = value;
                base.OnRightToLeftChanged(EventArgs.Empty);
            }
        }
    }
}
protected override CreateParams CreateParams
{
    get
    {
        CreateParams CP;
        CP = base.CreateParams;
        CP.ExStyle = CP.ExStyle | WS_EX_LAYOUTRTL ;
        return CP;
    }
}
// Rest of control code here
```

Globalizing Windows Forms | Localizing Applications | Bi-directional Support for Windows Applications | Windows Forms Inheritance | Implementing Mirror-Aware Controls for Windows Application with Visual Studio .NET (this link goes to the Microsoft.com Web site)

Creating Message Boxes for Bi-Directional Windows Applications

By default, a message box appears with left-to-right reading order. You can create messages boxes with right-to-left reading order and mirroring by passing certain parameters when you display the message box.

To create bi-directional message boxes

- Call the **MessageBox** class's Show method, and in the *options* parameter, pass the logical OR combination of the **RtlReading** and **RightAlign** members of the MessageBoxOptions enumeration. (The **RightAlign** member makes sure that wrapped text is aligned properly.)

  > **Note** The captions of buttons on the message box (such as "OK") are established by the Windows system locale, and you cannot set these during the call.

  The following example shows how to display a message box with right-to-left reading order and mirroring:

```
' Visual Basic
MessageBox.Show("Text", "Caption", _
   MessageBoxButtons.OK, MessageBoxIcon.Question, _
   MessageBoxDefaultButton.Button1, MessageBoxOptions.RtlReading _
      Or MessageBoxOptions.RightAlign)

// C#
MessageBox.Show("Text", "Caption",
    MessageBoxButtons.OK, MessageBoxIcon.Question,
    MessageBoxDefaultButton.Button1,
    MessageBoxOptions.RtlReading
    | MessageBoxOptions.RightAlign);
```

Globalizing Windows Forms | Localizing Applications | Creating Mirrored Windows Forms and Controls | Bi-directional Support for Windows Applications

Bi-directional Support for Web Applications

Visual Studio allows you to create Web applications that support bi-directional languages. Web applications have some issues that do not arise with client-based applications. For example, because the user interface is a browser that is not necessarily under your control, when you create your application, you must be aware of how users will access it.

Object Names in Web Applications

If your copy of Windows is configured with the appropriate language, Visual Studio allows you to use a bi-directional language when creating solutions, projects, and Web Forms pages. However, if the application will be accessed by people who do not have the proper language configuration, the names will not be processed properly.

For example, if you create Web pages with Arabic names, people without the Arabic Windows language pack will not be able to enter those names or even display them properly.

It is therefore recommended that in Web applications, you name elements using text that will be processed properly on all computers.

Culture Support

Culture and UI culture settings determine how an application works with dates, times, currency, and other information. Support for culture and UI culture is the same for bi-directional languages as it is for any other languages. For details, see Culture-Specific Classes for Global Windows Forms and Web Forms.

Encoding

ASP.NET handles all text as Unicode, and therefore supports bi-directional languages inherently. However, you must still set encoding options to specify what encoding is used to exchange information with browsers, and what encoding to apply to the application's files. You can do this by setting the `responseEncoding`, `requestEncoding`, and `fileEncoding` options in the application's Web.config file. For details, see Editing the Web.config File for Web Forms Globalization. Alternatively, you can set encoding options for individual pages by setting the encoding attributes in the @ Page directive.

Right-To-Left Support

When you create Web Forms pages, you can set the **dir** (direction) attribute. This specifies whether you want the page to use uses left-to-right or right-to-left reading order. However, it is up to the user's browser to implement the appropriate behavior. For details, see Displaying Right-to-Left Text Using HTML Tags for Globalization.

Flow and Grid Layout

In Grid layout, controls are positioned on the page using x and y coordinates. When the page is set to use right-to-left reading order, the x and y coordinates use the top right corner as their origin. In some cases, the page displays in the browser somewhat differently than it does in Design view of the Web Forms Designer. Therefore, for greatest precision when laying out pages that will be displayed in right-to-left reading order, it is recommended that you use flow layout. For details, see Positioning HTML Elements in Design View.

Web Forms Controls

HTML and ASP.NET server controls support Unicode and bi-directional languages. For example, the controls support right-to-left reading order, and text-entry controls such as the **TextBox** control allow you to enter Arabic or Hebrew text. The **Calendar** control supports localized dates (such as Hijri for Arabic) and bi-directional text.

There are small issues with some controls when they are used with bi-directional languages. For details, see Web Forms Controls in Bi-Directional Applications.

Web Forms Controls in Bi-Directional Applications | Globalizing Web Forms Pages | Localizing Applications | Visual Studio .NET With Arabic Language Support (this link goes to the Microsoft.com Web site)

Web Forms Controls in Bi-Directional Applications

You can use HTML and ASP.NET Web controls in applications with bi-directional text.

Control Reading Order

By default, controls inherit the reading order from the page they are in (that is, from the setting of the page's DIR attribute). You can set the reading order for individual controls as well. HTML controls expose a **dir** property that you can set in the Properties window. For ASP.NET controls, you set the **dir** property in HTML view. For details, see Displaying Right-to-Left Text Using HTML Tags for Globalization.

Displaying Numerals

The **DropDownList** and **ListBox** controls always display Latin numerals, even if the regional settings normally display Hindi numerals.

Validation Controls

For the most part, the ASP.NET validation Web server controls support bi-directional languages. Note the following:

- The validation controls do not ignore diacritics for the Arabic language.
- In the **RegularExpressionValidator** control, add the \W specifier to support characters in bi-directional languages. For example, the following regular expression is used to validate an email expression:

  ```
  \w+([-+.]\w+)*@\w+([-.]\w+)*\.\w+([-.]\w+)*
  ```

  The corresponding regular expression for multilingual text would be:

  ```
  (\w+|\W+)([-+.](\w+|\W+))*@(\w+|\W+)([-.](\w+|\W+))*\.(\w+|\W+)([-.](\w+|\W+))*
  ```

  For more details about regular expressions, see .NET Framework Regular Expressions.

Clipping

Under some circumstances, controls might clip text when set to right-to-left reading order. You can overcome this problem by padding the control's display with a style setting such as the following:

```
style="PADDING-RIGHT: 5px"
```

Creating and Retrieving Resources

In addition to containing executable code, applications will frequently contain nonexecutable data in the form of resources. Resources represent embedded data, such as strings or images, which can be retrieved at run time and displayed in the user interface. A common use for resources is localization of Windows Forms applications. Although resource management is handled in localization by the automatic creation of satellite assemblies, you can also manually retrieve and display resources at run time. The topics in this section demonstrate how to create resource files and resource assemblies, and how to retrieve them at run time.

In This Section

Creating and Editing Resource Files with ResEditor
Explains how to use the ResEditor application to create and edit resource files.
Embedding Resource Files in Applications
Describes how to add a resource file to an application.
Creating Resource Assemblies
Describes how to create resource-assemblies that can be updated without needing to recompile the solution.
Retrieving Resources with the ResourceManager Class
Explains how to use the **ResourceManager** class to retrieve resources at run time.

Related Sections

Globalization and Localization Namespaces in Visual Studio
Provides links to topics that describe how to use automatic globalization and localization for Windows Forms.
Common Resource Concepts
Provides detailed information about additional resource-related classes in the .NET Framework.

Creating and Editing Resource Files with ResEditor

The .NET Framework includes a sample application called ResEditor that facilitates creating and editing resource files. The ResEditor application allows you to create binary resource files (.resources) as well as XML resource files (.resX).

Building ResEditor

ResEditor is provided as source code with the .NET Framework SDK. Before you can use ResEditor, you must build it using the supplied batch file.

To build the ResEditor Application

1. Start Windows, and then click the **Start** button, point to **All Programs**, then **Visual Studio .NET 2003**, then **Visual Studio .NET Tools**, then **Visual Studio .NET Command Prompt** to open the Visual Studio .NET command prompt.
2. At the command prompt, change the directory to the SDK\v1.1\Samples\Tutorials\resourcesandlocalization\reseditor folder as shown below:

   cd \Program Files\Microsoft Visual Studio .NET 2003\SDK\v1.1\Samples\Tutorials\resourcesandlocalization\reseditor

3. At the command prompt, type **Build**, then press the ENTER key to build the application.

   ResEditor is built and the executable is placed in the \Program Files\Microsoft Visual Studio .NET\FrameworkSDK\Samples\Tutorials\resourcesandlocalization\reseditor folder.

Creating Resource Files

After ResEditor has been built, you can use it to create resource files.

To create a resource file with ResEditor

1. In **Windows Explorer**, browse to the directory that contains the **ResEditor** executable file.
2. Double-click the **ResEditor** icon to start the application.
3. From the **Add** drop-down menu, choose the type of resource you want to add.
4. Type the name of the resource in the **Add** text box, then click the **Add** button to add the resource entry to the file.
5. In the main pane, click the cell next to the resource name to specify a value.

   - For **String** resources, type the appropriate string into the box.
   - For **Image** and other types of resources, browse to the appropriate file.

6. Repeat steps 2, 3, and 4 for each resource you want to add to your file.
7. On the **File** menu, click **Save As** to save your file. You can save your file as either a .resources file or a .resX file.

Editing Existing Resource Files

You can also use ResEditor to edit exisitng resource files. You can use ResEditor to edit either .resources files or .ResX files.

To edit an existing resource file with ResEditor

1. In **Windows Explorer**, browse to the directory that contains the **ResEditor** executable file.
2. Double-click the **ResEditor** icon to start the application.
3. On the **File** menu, click **Open**.
4. Browse to the appropriate resource file in the **Open a Resource File** dialog box.

   The resource file opens and the resources it contains are displayed in the main pane.

5. If you want to change the value of any resource, click the cell next to the resource name and specify the correct value.

   - For **String** resources, type the appropriate string into the box.
   - For **Image** and other types of resources, browse to the appropriate file.

6. If you want to rename any of the resources, do the following:
   a. Highlight the resource you want to rename by clicking it.
   b. Type the new name in the **Rename** text box.

   c. Click the **Rename** button to apply the new name.
7. If you want to delete a resource, highlight the resource by clicking it and choose **Delete** from the **Resources** menu.
8. When you have finished editing your resource file, choose **File** then **Save As** to save your file.

Retrieving Resources with the ResourceManager Class | Embedding Resource Files in Applications | Creating Resource Assemblies

Embedding Resource Files in Applications

After you have created resource files, it is easy to add them to your application. Binary resource files (.resources) or XML resource files (.resX) can be added directly to your project. When your project is compiled, the resources files will be compiled as well. You can retrieve embedded resources (resources that have been compiled into a .dll file) by using the **ResourceManager** class. For more information, see Retrieving Resources with the ResourceManager Class.

If you want to frequently update resources in a program without having to recompile the entire solution, create a resource assembly. For more information, see Creating Resource Assemblies.

To add a resource file to your project

1. Create the resource file. For more information, see Creating and Editing Resource Files with ResEditor.
2. From the **Project** menu, choose **Add Existing Item**.

   The **Add Existing Item** dialog box opens.

3. Browse to the resource file that you want to add to your project. This can be either a .resources file or a .resX file. Select the appropriate file.
4. From the **Build** menu, choose **Build Solution** to embed your resource file in your compiled project.

See Also

Retrieving Resources with the ResourceManager Class | Creating and Editing Resource Files with ResEditor | Creating Resource Assemblies

Embedding Image Resources in a Project

Managing image resources as separate files can introduce complexities at deployment time. If you like the convenience of packaging images with your assemblies, you can add images to your project as embedded resources.

The following procedures show how to embed an image in your project and display it on a form.

To add an image to your project as an embedded resource

1. On the **Project** menu, choose **Add Existing Item**.
2. Navigate to the image you want to add to your project. Click the **Open** button to add the image to your project's file list.
3. Right-click the image in your project's file list and choose **Properties**. The Properties window appears.
4. Find the **Build Action** property in the Properties window. Change its value to **Embedded Resource**.

At this point, you can build the project. Your image will be compiled into your project's assembly.

To load the image programmatically and display it on a form

1. Import the System.Reflection and System.IO namespaces.
2. Choose an appropriate place in your code to load the image. The following example uses the form's **Load** event handler.

   The example code first uses reflection to get a reference to the assembly that is currently running.

   Then the example opens a stream on the embedded image. The name used to refer to the image takes this form:

   <namespace>.<image name>.<format>

   where **namespace** is the namespace for the project, **image name** is the name of the image, and **format** is the encoding format (for example, "bmp" or "jpg"). The example uses the string "EmbeddingExample.image1.bmp" to load the image.

   Finally, the example creates a **Bitmap** object from the image stream, assigns it to a **PictureBox** control, sizes the form to fit the image, and adds the **PictureBox** control to the form.

```
' Visual Basic
Private Sub Form1_Load(ByVal sender As System.Object, ByVal e As _
System.EventArgs) Handles MyBase.Load

        Dim myAssembly As System.Reflection.Assembly = _ System.Reflection.Assembly.GetEx
ecutingAssembly()
        Dim myStream As Stream = _ myAssembly.GetManifestResourceStream("EmbeddingExample
.image1.bmp")
        Dim image As New Bitmap(myStream)

        Me.ClientSize = New Size(image.Width, image.Height)

        Dim pb As New PictureBox
        pb.Image = image
        pb.Dock = DockStyle.Fill
        Me.Controls.Add(pb)
End Sub

// C#
private void Form1_Load(System.Object sender, System.EventArgs e)
    {
        System.Reflection.Assembly myAssembly = System.Reflection.Assembly.GetExecutingAs
sembly();
        Stream myStream = myAssembly.GetManifestResourceStream("EmbeddingExample.image1.b
mp");
        Bitmap image = new Bitmap(myStream);

        this.ClientSize = new Size(image.Width, image.Height);
```

```
        PictureBox pb = new PictureBox();
        pb.Image = image;
        pb.Dock = DockStyle.Fill;
        this.Controls.Add(pb);
    }
```

At this point, you can build and run the project.

Embedding Resource Files in Applications | Resource File Naming Conventions

Creating Resource Assemblies

Resource assemblies are useful when you need to frequently update resources in a program without having to recompile the entire solution. By placing all of your resources into a resource-only assembly, you can update the assembly as needed without having to recompile your application. Resources compiled into resource assemblies can be retrieved using the **ResourceManager** class. For more information, see Retrieving Resources with the ResourceManager Class.

To create a resource-only assembly

1. Create a new application with the **Empty Project** template.
2. From the **Project** menu, choose **Add Existing Item** to add your resource files to your project.
3. In **Solution Explorer**, right-click your project and choose **Properties** from the shortcut menu to open the **Project Property Pages**.
4. In the **Output Type** drop-down menu, change the output type of your project to **Class Library**.

   This will cause your assembly to be compiled as a .dll file.

5. From the **Build** menu, choose **Build <your project>** where <your project> is the name of your project.

   Your resources are compiled into the assembly.

See Also

Retrieving Resources with the ResourceManager Class | Embedding Resource Files in Applications | Creating and Editing Resource Files with ResEditor | Assemblies

Retrieving Resources with the ResourceManager Class

You can use the ResourceManager Class to retrieve *embedded resources* (resources that have been compiled into an application or class library) at run time. Each instance of the **ResourceManager** class is associated with an assembly and manages retrieval of the resources embedded in that assembly.

To retrieve a resource

1. Create a reference to the assembly that contains the resources you want to access. If the resource-containing assembly has not been loaded, it must be loaded at this time.
2. Create an instance of **ResourceManager** class to retrieve the resources.
3. Specify the base name of the embedded file and provide a reference to the assembly that contains the resources.

   Note The base name of an embedded resource file is the name of the namespace that the resource file is embedded and the name of the file without any extensions. For example, the base name of a file named Resource1.resX in the myApplication namespace would be myApplication.Resource1.

4. Call the ResourceManager.GetString Method or ResourceManager.GetObject Method to retrieve your resources.

   - To retrieve **String** resources, call the **GetString** method.
   - To retrieve resources of other types, call the **GetObject** method. Resources retrieved by means of the **GetObject** method must be explicitly converted to the appropriate type.

Example

```
' Visual Basic .NET
' Gets a reference to the same assembly that
' contains the type that is creating the ResourceManager.
Dim myAssembly As System.Reflection.Assembly
myAssembly = Me.GetType.Assembly

' Gets a reference to a different assembly.
Dim myOtherAssembly As System.Reflection.Assembly
myOtherAssembly = System.Reflection.Assembly.Load("ResourceAssembly")

' Creates the ResourceManager.
Dim myManager As New _
   System.Resources.ResourceManager("ResourceNamespace.myResources", _
   myAssembly)

Dim myString As System.String
Dim myImage As System.Drawing.Image
myString = myManager.GetString("StringResource")
myImage = CType(myManager.GetObject("ImageResource"), _
    System.Drawing.Image)

// C#
// Gets a reference to the same assembly that
// contains the type that is creating the ResourceManager.
System.Reflection.Assembly myAssembly;
MyAssembly = this.GetType().Assembly;

// Gets a reference to a different assembly.
System.Reflection.Assembly myOtherAssembly;
myOtherAssembly = System.Reflection.Assembly.Load("ResourceAssembly");

// Creates the ResourceManager.
System.Resources.ResourceManager myManager = new
   System.Resources.ResourceManager("ResourceNamespace.myResources",
   myAssembly);

// Retrieves String and Image resources.
System.String myString;
System.Drawing.Image myImage;
```

```
myString = myManager.GetString("StringResource");
myImage = (System.Drawing.Image)myManager.GetObject("ImageResource");
```

Securing Applications Portal

Security is a watchword for application development, especially in applications that will be accessible to users across a network. To create a secure application, you must understand the security risks that your application is subject to. You must also be familiar with the techniques used to prevent unauthorized access to your application and ensure data integrity.

In the Visual Basic and Visual C# Documentation

Introduction to Web Application Security
Provides an overview of security for Web applications, describing what types of issues you need to think about when creating applications in Visual Studio.
Windows Forms Security
Describes the security model for Windows applications, including code-based security and security schemes from the operating system.
Security Considerations for ASP.NET Web Applications
Links to the topics that provide an introduction to security in Web applications.
Setting Web Permissions
Describes how to control who can gain access to your Web project files and what level of access individuals have to the application.
Code Security in Components
Explains the issues you must deal with when designing secure components: how to ensure that your code will run where it is deployed, how to protect your component against malicious use, how to request permissions for component code, and how to assure users of your component's source and authenticity.
Adding Imperative Security Checks to Components
Describes how to protect specific blocks of code by requiring appropriate permissions for them.
Adding Security Attributes to Components
Describes how to use attributes to request permissions for your assembly before any code members are modified.
Security Ramifications of Event Logs
Describes the access rights needed to perform common tasks with the **EventLog** component.
Message Queue Security
Presents an overview of the security features of Microsoft Message Queueing.
Specifying the Security Context for Services
Describes how to determine the security context in which your services will run.
Introduction to the EventLog Component
Describes how to interact with the Windows Security log, which tracks security changes and possible breaches.
Security and Localized Satellite Assemblies
Describes strong naming requirements for your localized applications.

Additional Information

Securability Overview
Discusses how to provide security to an application and its data.
Best Practices for Securability
Presents best practices for creating securable applications.
Securing Applications
Provides information from the *.NET Framework Developer's Guide* about classes and services that enable developers to write secure code and enable system administrators to customize the access that code has to protected resources.
Access Control
Presents and overview of what access controls lists (ACLs) are and their role in securing applications.
Code Access Security Basics
Defines code access security in .NET, and describes the main tasks involved in implementing and working with it.
Decision Chart
Provides a graphical, linked guide to decisions about designing your application.
Security Namespaces in Visual Studio
Lists the major namespaces for security and provides links to .NET Framework reference topics about the types (classes, structures, enumerations, delegates, and interfaces) in the namespaces, as well as links to topics about using them in Visual Basic and Visual C# applications.
.NET Framework Security
Provides information from the *.NET Framework Developer's Guide* about Web application security, code-access security, and role-based security.
Security Model

Describes the design choices you face when designing the architecture of your distributed application, including choices that affect authentication, authorization, impersonation, and database security.

Macros Security and Sharing Issues

Describes the main security considerations for macro development, including intellectual property protection and virus avoidance and protection.

Visual Basic Code Example Topics

Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.

Troubleshooting Problems Portal

As you develop Visual Studio applications, you might run into problems or errors that you do not immediately know how to resolve. In the topics listed below, you can find solutions to problems that might arise during your development process.

Project Troubleshooting

Troubleshooting Web Projects
Describes solutions to common problems that may occur when creating or opening Web projects in Visual Studio .NET.
Troubleshooting Broken References
Describes solutions for various problems that you might encounter when adding references to files and components.
Web Access Failed Dialog Box
Provides help for error messages that may arise when creating and opening Web projects.

Language Troubleshooting

Visual Basic Compiler Errors
Discusses the Visual Basic compiler errors that occur when the compiler encounters problems in your code.
Visual Basic Run-Time Errors
Discusses the Visual Basic run-time errors that occur when an application attempts to perform an action that the system cannot execute.
Upgrading from Visual Basic 6.0
Describes the changes you need to be aware of when upgrading your applications to Visual Basic .NET.
Language Changes in Visual Basic
Describes the language-specific changes between Visual Basic 6.0 and Visual Basic .NET.

Data Troubleshooting

Troubleshooting Data Access in Visual Studio .NET
Suggests how to fix common problems that arise when working with data access in Visual Studio .NET.

Components and Component Authoring Troubleshooting

Troubleshooting FileSystemWatcher Components
Describes solutions for various situations you might encounter when working with the **FileSystemWatcher** component.
Troubleshooting MessageQueue Components
Describes the solutions for a situation you might encounter when working with the **MessageQueue** component.
Troubleshooting Control and Component Authoring
Explains how to fix common problems when creating your own control or component.
Troubleshooting Inherited Event Handlers in Visual Basic .NET
Explains how to fix common issues with event handlers in inherited components.

Web Applications Troubleshooting

Troubleshooting Web Projects
Describes solutions to common problems that may occur when creating or opening Web projects in Visual Studio .NET.
Web Access Failed Dialog Box
Provides help for error messages that may arise when creating and opening Web projects.

Windows Applications Troubleshooting

Troubleshooting: Debugging Windows Services
Describes how you can debug a Windows service application using all of the standard debugging functionality of Visual Studio.

Deployment Troubleshooting

Troubleshooting Deployment
Describes solutions for various problems that you might encounter when creating deployment projects and deploying applications.

Extensibility Troubleshooting

Troubleshooting Visual Basic and Visual C# Extensibility
Describes solutions to common problems that may occur when developing macros, add-ins, and wizards.

Upgrading Troubleshooting

Troubleshooting Applications Upgraded from Visual Basic 6.0
Describes some known issues that are not detected by the upgrading tools and how to address them.
Upgrading from Visual Basic 6.0
Describes the changes you need to be aware of when upgrading your applications to Visual Basic .NET.
Language Changes in Visual Basic
Describes the language-specific changes between Visual Basic 6.0 and Visual Basic .NET.
Upgrading Visual InterDev 6.0 Applications to Visual Studio .NET
Describes how to upgrade a Visual InterDev 6.0 project so you can take advantage of features provided by the .NET Framework.

Additional Information

Visual Basic Code Example Topics
Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.
Getting Help from Microsoft Product Support Services
Describes various ways to get technical support.
Visual Studio .NET Software Requirements
Lists the features supported in various versions of the Windows operating system, as well as solutions for some common problems.
Visual Studio .NET Editions
Lists the features supported in the Professional, Enterprise Developer, Enterprise Architect, and Academic editions of Visual Studio.
Visual Basic Standard Edition Features
Lists the features supported in this edition of Visual Basic, which may explain why something is not working as expected.
Visual C# Standard Edition Features
Lists the features supported in this edition of Visual C#, which may explain why something is not working as expected.

Testing Scalability and Performance Portal

An important part of developing Visual Studio applications is to design and build it for optimal performance. This requires that you understand the performance implications of your application design. In addition, you must know how to test your application to get objective measures of its performance under a variety of conditions.

Visual Basic and C# Scalability and Performance Topics

Monitoring Performance Thresholds
Provides basic information on monitoring Microsoft Windows 2000 performance thresholds.
Tracing and Instrumenting Applications in Visual Basic and Visual C#
Provides information on how to use trace statements to monitor your application's performance.

Visual Studio Scalability and Performance Topics

Scalability
Presents information on designing your application to allow for maximum increase in capacity as resources change, testing your application's scalability, and following best practice recommendations.
Performance
Presents information on designing your application for maximum performance, testing your application's performance, and following best practice recommendations.
Testing for Performance
Describes how to test to determine whether your application meets the performance guidelines you have set.
Testing for Reliability
Describes how to test to determine whether your application meets the reliability guidelines you have set.
Testing for Scalability
Describes how to test to determine whether your application meets the scalability guidelines you have set.
Instrumentation Guidelines
Describes how to use Visual Studio Analyzer to help track your application's performance.

Accessing Data

Most Visual Basic and Visual C# applications revolve around reading and updating information in databases. To allow data integration in distributed, scalable applications, Visual Studio .NET provides support for a new generation of data access technology: ADO.NET.

In This Section

Data Walkthroughs
Lists topics that illustrate how to perform common data-related tasks.
Code for Data Access
Provides code examples for common data tasks.
Troubleshooting Data Access in Visual Studio .NET
Suggests how to fix common problems that arise when working with data access in Visual Studio .NET.
Introduction to Distributed Applications and Data Integration
Provides a general introduction to the concepts of data access in applications you create with Visual Basic and Visual C#.
Connecting to Data Sources with ADO.NET
Provides topics about creating and working with connection objects in Visual Studio.
ADO.NET Data Adapters
Provides topics about defining the SQL statement or stored procedure calls that you use to fill datasets and write data back to the database.
ADO.NET Datasets
Provides topics about what datasets are and how to use them.
Filtering and Sorting in Datasets
Provides topics about viewing the data in a dataset in different ways by selecting subsets of records or sorting.
Relationships in ADO.NET Datasets
Provides topics about working with dataset tables that have a parent-child relationship.
Performing Database Operations Directly
Provides topics about how to execute SQL statements and stored procedures directly and work with the results they return.
Dataset Updates in Visual Studio .NET
Provides topics about making changes in datasets and then writing those changes back to a data source.
XML Schemas and Data
Provides topics about creating XML schemas that describe the structure of datasets.

Related Sections

Data Design
Provides topics that discuss the fundamental concepts of designing data storage and access for applications.
Visual Basic Code Example Topics
Lists quickstart-like code examples that help you perform common tasks in Visual Basic .NET.
Decision Chart
Provides an interactive guide to help you choose which approach or technology to use, as well as links to more information.
What's New in Data
Discusses data access features that are new in Visual Studio .NET.
Windows Forms Data Architecture
Provides topics on how data binding works in Windows Forms and how to bind controls to a data source.
Data Access in Web Forms Pages
Provides topics on the issues associated with data binding in Web Forms pages and how to bind controls to a data source.

Data Walkthroughs

These step-by-step topics cover common data and XML scenarios.

> **Tip** If you are new to ADO.NET, try one of the Windows Forms or Web Forms data walkthroughs before trying one of the general data walkthroughs.

In the Visual Basic and Visual C# Documentation

Windows Forms Data-Access Walkthroughs

Simple Data Access in a Windows Form
Describes the basic steps required for accessing SQL Server data via a dataset in a read-write Windows Form.
Displaying Data in a Windows Form Using a Parameterized Query
Describes how to create a dataset containing only selected records, based on criteria that users provide at run time in a Windows Form.
Creating a Master-Detail Windows Form
Describes how to create a parent-child relationship in a dataset and display related records in a Windows Form.

Web Forms Data-Access Walkthroughs

Displaying Data in a Web Forms Page
Illustrates a basic data-access scenario, providing step-by-step instructions for how to create a Web Forms page that displays data in a grid control.
Creating Read-Only Data Access in a Web Forms Page
Describes how to use an ADO.NET data command and data reader to provide optimized access to read-only data in a Web Forms page.
Updating Data Using a Database Update Query in Web Forms
Describes the basic techniques of creating a Web Forms page that uses a data command to update the database.
Using a DataGrid Web Control to Read and Write Data
Gives step-by-step details on how to use a grid control to allow users to view and edit data.
Creating Paged Data Access Using a Web Forms Page
Describes how to create a Web Forms page that allows users to view data records a few records at a time, paging back and forth to view earlier and later records.

General Data Walkthroughs

Creating a Distributed Application
Illustrates how to create an application with a middle-tier component (an XML Web service) that is used to get and update data.
Creating a Dataset with Tables, Keys, and One-to-Many Relationships
Describes the steps to create a dataset and use it to validate data in a one-to-many or keyed relationship.
Handling a Concurrency Exception
Describes how to use the **DBConcurrencyException** object to identify concurrency exceptions and the actual record that caused the error.
Mapping Data Source Tables to Dataset Tables
Describes how to load data from a database into a dataset based on a different schema using data adapter table and column mappings.

XML Data and XML Schema Walkthroughs

Creating an XML File with an Associated XML Schema
Describes how to create an XML file and a schema, associating the two, and working on the XML file in the designer's XML view.
Creating an XML Schema with the XML Designer
Describes the steps to create an XML purchase order schema as part of a Windows application.
Reading XML Data into a Dataset
Shows how to load XML data into a dataset, display it in a Windows Forms **DataGrid** control, then display an XML Schema for the XML file in a text box.
Displaying an XML Document in a Web Forms Page using Transformations
Gives step-by-step details on how to read an XML file and display it in different ways on a Web Forms page.

Walkthroughs in Visual Basic and Visual C#

Shows a complete list of walkthroughs related to managed development in Visual Basic and Visual C#.

Visual Basic Code Example Topics

Shows quickstart-like code examples that help you perform common tasks in Visual Basic .NET.

Code for Data Access

This topic is designed to help you find code that demonstrates how to perform common data-programming tasks in Visual Basic .NET. The following categories are represented in the list below:

• Datasets • Data Views • Updating Datasets and Data Sources	• Data Commands • Concurrency • Relations • Related Code Examples

You can also find sample code for data access in these locations:

- Creating and Filling Datasets Example Topics
- Manipulating Data Example Topics
- Visual Basic Sample Applications
- Visual Basic QuickStarts and Other Samples
- Accessing Data with ADO.NET

Datasets

Example of...

Accessing columns in datasets

Filling datasets

Filling datasets with a parameterized query

Creating a simple Windows application that uses a dataset

Creating a simple Windows application that uses a parameterized query

Creating a simple Web application that uses a dataset

Creating a simple distributed application that exchanges information in datasets

Creating a simple application that maps data tables to a dataset

Sorting a data table in a dataset

Filtering (selecting) a data table in a dataset

Data Views

Example of...

Sorting a dataset using a data view

Filtering (selecting) in a dataset using a data view

Finding records in a data view

Reading records using a data view

Updating records using a data view

Inserting records using a data view

Deleting records using a data view

Working with multiple data views

Updating Datasets and Data Sources

Example of...

Updating existing dataset records

Creating a simple Windows application that updates a database

Creating a simple Web application that updates a database

Creating a simple Web application that updates a database using a grid

Inserting records into a dataset

Deleting records from a dataset

Merging datasets

Turning off dataset constraints

Committing dataset changes

Sending dataset changes to the data source

Handling data-update errors

Data Commands

Example of...

Creating parameterized queries

Creating a simple Web application that displays information in a grid

Executing queries that return a result set

Creating a simple Web application that displays paged data

Executing update, insert, or delete queries

Executing database (DDL) commands

Executing commands that return a scalar value

Concurrency

Example of...

Creating a simple application that implements concurrency checking

Handling concurrency errors

Relations

Example of...

Working with data in related tables

Troubleshooting Data Access in Visual Studio .NET

This topic lists the following common issues that arise when working with data access in Visual Studio .NET.

Cannot Access a Data Base at Run Time that I Can Access at Design Time

After Reconfiguring a Data Adapter, Filling a Dataset Throws an Exception

Getting the 'Connection property has not been initialized' Error

Incorrect or Missing Output Parameters are Returned When Executing a SQL Command

Getting the 'The .NET Data SQL Provider (System.Data.SqlClient) requires Microsoft Data Access Components (MDAC) version 2.6 or later' Error

Getting an Unexpected Exception When Attempting to Commit or Roll Back a Transaction

Getting an InvalidOperationException When Attempting to Remove Tables from a Dataset

Cannot Access a Database at Run Time that I Can Access at Design Time

This is most likely the result of the user name and password passed at run time being denied access to the database. Resolution depends on the authentication and authorization methods being used in the database, as well as the connection string.

Some common configurations that cause this problem are:

- Selecting the **Use a specific username and password** option and not selecting the **Allow saving password** option when completing the Data Link Properties Dialog Box. In this scenario you are prompted for a username and password when attempting to connect to the data source at design time. For run-time connectivity, you need to incorporate functionality into your application to pass the proper username and password to the data source.
- Not setting up permission for the ASPNET user in your data source. For information on how ASP.NET requests permissions to data, see Access Permissions for Web Applications.

Things to check:

- Verify the username and password that your application is using have proper permissions to access the data source.
- Verify the user has the correct permission settings in the database.
- Verify there is network connectivity between the machine running the application and the data source.

After Reconfiguring a Data Adapter, Filling a Dataset Throws an Exception

Reconfiguring a data adapter does not automatically regenerate the dataset. The dataset needs to be synchronized with the new data-adapter configuration. Regenerating the dataset should fix this problem.

To regenerate a Dataset from a configured data adapter

1. Select the form that contains the data adapter and open it in **Design** view.
2. On the **Data** menu, click **Generate Dataset**.

   The Generate Dataset Dialog Box opens.

3. In the **Choose which table(s) to add to the dataset** area, select the table associated with the reconfigured data adapter.
4. Click **OK**.

The following table provides links to related information.

For more information on...	See...
DataSet Class	Introduction to Datasets
DataAdapter Class	Introduction to Data Adapters

Getting the 'Connection property has not been initialized' Error

This is most likely the result of command objects that no longer contain a reference to a valid data connection object. This is typically caused by deleting and recreating an existing connection object.

Applications with Data Adapters

Reconfigure the data adapter to set the **Connection** property for the adapter's **Command** objects. For more information about data adapters, connections, and commands, see Using .NET Data Providers to Access Data.

To reconfigure a data adapter

1. Select the form that contains the data adapter(s) and open it in **Design** view.
2. Select the data adapter in the component tray.

3. On the **Data** menu, click **Configure Data Adapter** .

   The Data Adapter Configuration Wizard opens.

4. Complete the wizard. For more information, see Data Adapter Configuration Wizard.
5. Repeat this process from step 2 for each affected data adapter.

Applications with Individual Command Objects

Set the **Connection** property to a valid connection object.

To set the Connection property of a Command object

1. Select the form that contains the command(s) and open it in **Design** view.
2. Select the command object in the component tray.
3. Set its **Connection** property to a valid connection object.
4. Repeat this process from step 2 for each affected command.

Incorrect or Missing Output Parameters Are Returned When Executing a SQL Command

This most likely results from incorrect setting of the parameter's **Direction** property. The parameter's **Direction** property is set to a value defined in the ParameterDirection Enumeration.

- Verify the parameter's **Direction** property is set to a value that that can receive data (Output for output parameters).
- Verify the parameter's data type is the same as the data type of the expected return value.

> **Note** Output parameters are returned at the end of the data stream, so if you are using the **DataReader** object, you must close it or read to the end of the data before the output parameters are visible.

For more information on output parameters not being returned, as well as a code sample, search for Q308051 on the Microsoft Product Support Services Web site (http://support.microsoft.com). Select **Article ID** as the Search option.

Getting the 'The .NET Data SQL Provider (System.Data.SqlClient) requires Microsoft Data Access Components (MDAC) version 2.6 or later' Error

The Microsoft .NET Framework SDK and the .NET Framework redistributable package do not include the MDAC installation. All .NET applications that use data-access functionality require MDAC 2.6 or later (MDAC 2.7 is recommended). The latest version of MDAC is available as a download from the Microsoft Web site (http://www.microsoft.com).

Because Visual Studio .NET installs MDAC 2.7 by default, this error is most likely to occur when deploying to a machine that does not have Visual Studio .NET installed.

When you deploy your application, you can have the setup check the version of MDAC on the computer being deployed to. For more information, see Adding a Launch Condition for Microsoft Data Access Components.

Getting an Unexpected Exception When Attempting to Commit or Roll Back a Transaction

When an error at the data source causes a transaction to be immediately rolled back, one of the following errors may be raised in your application:

- "The COMMIT TRANSACTION request has no corresponding BEGIN TRANSACTION"
- "The ROLLBACK TRANSACTION request has no corresponding BEGIN TRANSACTION"

Although this behavior is by design, it is always best to call methods that access external data sources (such as the **Commit** and **Rollback** methods) from within a **Try...Catch** statement. For more information, see Using the Try/Catch Block to Catch Exceptions.

Getting an InvalidOperationException When Attempting to Remove Tables from a Dataset

When a dataset is bound to a XmlDataDocument calling the **Clear** method throws the following exception:

System.InvalidOperationException: Cannot add or remove tables from the DataSet once the DataSet is mapped to a loaded XML document.

Clearing the data from a dataset bound to a **XmlDataDocument** object requires navigating the table and removing the individual DataRow objects. For more information on removing data rows from a data table, see Deleting Records in a Dataset and DataRowCollection.RemoveAt Method.

Introduction to Data Access with ADO.NET

As you develop applications using ADO.NET, you will have different requirements for working with data. In some cases, you might simply want to display data on a form. In other cases, you might need to devise a way to share information with another company.

No matter what you do with data, there are certain fundamental concepts that you should understand about the data approach in ADO.NET. You might never need to know some of the details of data handling — for example, you might never need to directly edit an XML file containing data — but it is very useful to understand the data architecture in ADO.NET, what the major data components are, and how the pieces fit together.

This introduction presents a high-level overview of these most important concepts. The topic deliberately skips over many details — for example, there is much more to datasets than what is mentioned here — in favor of simply introducing you to ideas behind data integration in ADO.NET.

> **Note** When you deploy an application that includes Visual Studio data-access components, you must make sure that the user installing the application has version 2.7 or later of the Microsoft Data Access Components (MDAC). For more information, see Adding a Launch Condition for Microsoft Data Access Components.

ADO.NET Does Not Depend On Continuously Live Connections

In traditional client/server applications, components establish a connection to a database and keep it open while the application is running. For a variety of reasons, this approach is impractical in many applications:

- Open database connections take up valuable system resources. In most cases, databases can maintain only a small number of concurrent connections. The overhead of maintaining these connections detracts from overall application performance.
- Similarly, applications that require an open database connection are extremely difficult to scale up. An application that does not scale up well might perform acceptably with four users but will likely not do so with hundreds. ASP.NET Web applications in particular need to be easily scalable, because traffic to a Web site can go up by orders of magnitude in a very short period.
- In ASP.NET Web applications, the components are inherently disconnected from each other. The browser requests a page from the server; when the server has finished processing and sending the page, it has no further connection with the browser until the next request. Under these circumstances, maintaining open connections to a database is not viable, because there is no way to know whether the data consumer (the client) requires further data access.
- A model based on always-connected data can make it difficult and impractical to exchange data across application and organizational boundaries using a connected architecture. If two components need to share the same data, both have to be connected, or a way must be devised for the components to pass data back and forth.

For all these reasons, data access with ADO.NET is designed around an architecture that uses connections sparingly. Applications are connected to the database only long enough to fetch or update the data. Because the database is not holding on to connections that are largely idle, it can service many more users.

Database Interactions Are Performed Using Data Commands

To perform operations in a database, you execute SQL statements or stored procedures (which include SQL statements). You use SQL statements or stored procedures to read and write rows and perform aggregate functions, such as adding or averaging. You also use SQL statements or stored procedures to create or modify tables or columns, to perform transactions, and so on.

In ADO.NET you use data commands to package a SQL statement or stored procedure. For example, if you want to read a set of rows from the database, you create a data command and configure it with the text of a SQL Select statement or the name of a stored procedure that fetches records.

When you want to get the rows, you do the following:

1. Open a connection.
2. Call an execute method of the command, which in turn:
   a. Executes the SQL statement or stored procedure referenced by the command.
   b. Then closes the connection.

   The connection stays open only long enough to execute the statement or stored procedure.

When you call a command's execute method, it returns a value. Commands that update the database return the number of rows affected; other types of commands return an error code. If the command queries the database with a SELECT statement, the

command can return a set of rows. You can fetch these rows using a data reader, which acts as a very fast read-only, forward-only cursor. For more information, see Retrieving Data Using the DataReader.

> **Security Note** When using data commands with a CommandType property set to **Text**, carefully check information that is sent from a client before passing it to your database. Malicious users might try to send (inject) modified or additional SQL statements in an effort to gain unauthorized access or damage the database. Before you transfer user input to a database, you should always verify that the information is valid; it is a best practice to always use parameterized queries or stored procedures when possible. For more information, see Scripting Exploits.

If you need to perform more than one operation — for example, read some rows and then update them — you use multiple data commands, one for each operation. Each operation is performed separately. For example, to read the rows, you open the connection, read the rows, and then close the connection. When you want to update data, you again open the connection, perform the update, and then close the connection again.

Data commands can include parameters (specifically, a collection of parameter objects) that allow you to create parameterized queries such as the following:

```
Select * From customers Where (customer_id = @customerid)
```

You can then set the parameters at run time and execute the command to return or update the data you want.

Data Can Be Cached in Datasets

The most common data task is to retrieve data from the database and do something with it: display it, process it, or send it to another component. Very frequently, the application needs to process not just one record, but a set of them: a list of customers or today's orders, for example. Often the set of records that the application requires comes from more than one table: my customers and all their orders; all authors named "Smith" and the books they have written; and other, similar, sets of related records.

Once these records are fetched, the application typically works with them as a group. For example, the application might allow the user to browse through all the authors named "Smith" and examine the books for one Smith, then move to the next Smith, and so on.

In many cases, it is impractical to go back to the database each time the application needs to process the next record. (Doing so can undo much of the advantage of minimizing the need for open connections.) A solution, therefore, is to temporarily store the records retrieved from the database and work with this temporary set.

This is what a dataset is. A dataset is a cache of records retrieved from a data source. It works like a virtual data store: A dataset includes one or more tables based on the tables in the actual database, and it can include information about the relationships between those tables and constraints on what data the tables can contain.

The data in the dataset is usually a much-reduced version of what is in the database. However, you can work with it in much the same way you do the real data. While you are doing so, you remain disconnected from the database, which frees it to perform other tasks.

Of course, you often need to update data in the database (although not nearly as often as you retrieve data from it). You can perform update operations on the dataset, and these can be written through to the underlying database.

An important point is that the dataset is a passive container for the data. To actually fetch data from the database and (optionally) write it back, you use data adapters. A data adapter contains one or more data commands used to populate a single table in the dataset and update the corresponding table in the database. (A data adapter typically contains four commands, one each to select, insert, update, and delete rows in the database.) Therefore, a data adapter's **Fill** method might execute a SQL statement such as `SELECT au_id, au_lname, au_fname FROM authors` whenever the method is called.

Because a dataset is effectively a private copy of the database data, it does not necessarily reflect the current state of the database. If you want to see the latest changes made by other users, you can refresh the dataset by calling the appropriate **Fill** method.

One of the advantages of using datasets is that components can exchange them as required. For example, a business object in the middle tier might create and populate a dataset, then send it to another component elsewhere in the application for processing. This facility means that components do not have to individually query the database.

Datasets Are Independent of Data Sources

Although a dataset acts as a cache for data drawn from a database, the dataset has no actual relationship with the database. The dataset is a container; it is filled by SQL commands or stored procedures executed from a data adapter.

Because a dataset is not directly tied to a data source, it is a good integration point for data coming from multiple sources. For

example, some of the data in a dataset might come from your database, whereas other parts of it might come from a different database or a non-database source such as a spreadsheet. Some of the data in a dataset might arrive in a stream sent by another component. Once the data is in a dataset, you can work with it using a consistent object model, regardless of its original source.

Data Is Persisted as XML

Data needs to be moved from the data store to the dataset, and from there to various components. In ADO.NET the format for transferring data is XML. Similarly, if data needs to be persisted (for example, into a file), it is stored as XML. If you have an XML file, you can use it like any data source and create a dataset out of it.

In fact, in ADO.NET, XML is a fundamental format for data. The ADO.NET data APIs automatically create XML files or streams out of information in the dataset and send them to another component. The second component can invoke similar APIs to read the XML back into a dataset. (The data is not stored in the dataset as XML — for example, you cannot parse data in a dataset using an XML parser — but instead in a more efficient format.)

Basing data protocols around XML offers a number of advantages:

- XML is an industry-standard format. This means that your application's data components can exchange data with any other component in any other application, as long as that component understands XML. Many applications are being written to understand XML, which provides an unprecedented level of exchange between disparate applications.
- XML is text-based. The XML representation of data uses no binary information, which allows it to be sent via any protocol, such as HTTP. Most firewalls block binary information, but by formatting information in XML, components can still easily exchange the information.

For most scenarios, you do not need to know XML in order to use data in ADO.NET. ADO.NET automatically converts data into and out of XML as needed; you interact with the data using ordinary programming methods.

Schemas Define Data Structures

Although you do not need to know anything about XML to read and write to the database and work with datasets, there are situations in which working with XML is precisely the goal you are after. These are situations in which you are not accessing data, but instead, working with the design of data. To put it another way, in ADO.NET you use XML directly when you are working with metadata.

Datasets are represented as XML. The structure of the dataset — the definition of what tables, columns, data types, constraints, and so on are in the dataset — is defined using an XML Schema based on the XML Schema definition language (XSD). Just as data contained by a dataset can loaded from and serialized as XML, the structure of the dataset can be loaded from and serialized as XML Schema.

For most of the work you do with data in ADO.NET, you do not have to delve deeply into schemas. Typically, the Visual Studio .NET tools will generate and update schemas as needed, based on what you do in visual designers. For example, when you use the tools to create a dataset representing tables in your database, Visual Studio .NET generates an XML Schema describing the structure of the dataset. The XML Schema is then used to generate a typed dataset, in which data elements (tables, columns, and so on) are available as first-class members. For more information about typed datasets, see Introduction to Datasets.

However, there are times when you want to create or edit schemas yourself. A typical example is developing a schema in conjunction with a partner or client. In that case, the schema serves as a contract between you and the partner regarding the shape of the XML-based data you will exchange. In that situation, you will often have to map the schema elements to the structure of your own database. For more information about designing schemas, see XML Schemas and Data.

Components of ADO.NET

The following illustration shows the major components of an ADO.NET application.

ADO.NET Data Components

Benefits of ADO.NET

ADO.NET offers several advantages over previous versions of ADO and over other data access components. These benefits fall into the following categories:

Interoperability

ADO.NET applications can take advantage of the flexibility and broad acceptance of XML. Because XML is the format for transmitting datasets across the network, any component that can read the XML format can process data. In fact, the receiving component need not be an ADO.NET component at all: The transmitting component can simply transmit the dataset to its destination without regard to how the receiving component is implemented. The destination component might be a Visual Studio application or any other application implemented with any tool whatsoever. The only requirement is that the receiving component be able to read XML. As an industry standard, XML was designed with exactly this kind of interoperability in mind.

Maintainability

In the life of a deployed system, modest changes are possible, but substantial, architectural changes are rarely attempted because they are so difficult. That is unfortunate, because in a natural course of events, such substantial changes can become necessary. For example, as a deployed application becomes popular with users, the increased performance load might require architectural changes. As the performance load on a deployed application server grows, system resources can become scarce and response time or throughput can suffer. Faced with this problem, software architects can choose to divide the server's business-logic processing and user-interface processing onto separate tiers on separate machines. In effect, the application server tier is replaced with two tiers, alleviating the shortage of system resources.

The problem is not designing a three-tiered application. Rather, it is increasing the number of tiers after an application is deployed. If the original application is implemented in ADO.NET using datasets, this transformation is made easier. Remember, when you replace a single tier with two tiers, you arrange for those two tiers to trade information. Because the tiers can transmit data through XML-formatted datasets, the communication is relatively easy.

Programmability

ADO.NET data components in Visual Studio encapsulate data access functionality in various ways that help you program more quickly and with fewer mistakes. For example, data commands abstract the task of building and executing SQL statements or stored procedures.

Similarly, ADO.NET data classes generated by the tools result in typed datasets. This in turn allows you to access data through typed programming. For example, consider the following line of code that accesses a data member in an untyped dataset:

```
' Visual Basic
If TotalCost > DataSet1.Tables("Customers").Rows(i)("AvailableCredit") Then

// C#
if (TotalCost > DataSet1.Tables["Customers"].Rows[i]["AvailableCredit"]) { }
```

The equivalent line to access a data member in a typed dataset looks like the following:

```
' Visual Basic
If TotalCost > DataSet1.Customers("Jones").AvailableCredit Then

// C#
if(TotalCost > DataSet1.Customers("Jones").AvailableCredit) { }
```

The code for the typed dataset is easier to read. It is also easier to write, because statement completion is provided. For example, "AvailableCredit" is among the list of choices for completing the following statement:

```
IF TotalCost > Customer.
```

Finally, the code for the typed dataset is safer, because it provides for the compile-time checking of types. For example, suppose that `AvailableCredit` is expressed as a currency value. If the programmer erroneously assigns a string value to `AvailableCredit`, the environment would report the error to the programmer during compile time. When working with untyped datasets, the programmer would not learn of the error until run time.

For more information about typed and untyped datasets, see Introduction to Datasets.

Performance

For disconnected applications, ADO.NET datasets offer performance advantages over ADO disconnected recordsets. When using COM marshalling to transmit a disconnected recordset among tiers, a significant processing cost can result from converting the values in the recordset to data types recognized by COM. In ADO.NET, such data-type conversion is not necessary.

Scalability

Because the Web can vastly increase the demands on your data, scalability has become critical. Internet applications have a limitless supply of potential users. Although an application might serve a dozen users well, it might not serve hundreds —or hundreds of thousands — equally well. An application that consumes resources such as database locks and database connections will not serve high numbers of users well, because the user demand for those limited resources will eventually exceed their supply.

ADO.NET accommodates scalability by encouraging programmers to conserve limited resources. Because any ADO.NET application employs disconnected access to data, it does not retain database locks or active database connections for long durations.

Comparison of ADO.NET and ADO

You can understand the features of ADO.NET by comparing them to particular features of ActiveX Data Objects (ADO).

In-memory Representations of Data

In ADO, the in-memory representation of data is the recordset. In ADO.NET, it is the dataset. There are important differences between them.

Number of Tables

A recordset looks like a single table. If a recordset is to contain data from multiple database tables, it must use a JOIN query, which assembles the data from the various database tables into a single result table.

In contrast, a dataset is a collection of one or more tables. The tables within a dataset are called data tables; specifically, they are DataTable objects. If a dataset contains data from multiple database tables, it will typically contain multiple **DataTable** objects. That is, each **DataTable** object typically corresponds to a single database table or view. In this way, a dataset can mimic the structure of the underlying database.

A dataset usually also contains relationships. A relationship within a dataset is analogous to a foreign-key relationship in a database —that is, it associates rows of the tables with each other. For example, if a dataset contains a table about investors and another table about each investor's stock purchases, it could also contain a relationship connecting each row of the investor table with the corresponding rows of the purchase table.

Because the dataset can hold multiple, separate tables and maintain information about relationships between them, it can hold much richer data structures than a recordset, including self-relating tables and tables with many-to-many relationships.

Data Navigation and Cursors

In ADO you scan sequentially through the rows of the recordset using the ADO **MoveNext** method. In ADO.NET, rows are represented as collections, so you can loop through a table as you would through any collection, or access particular rows via ordinal or primary key index. **DataRelation** objects maintain information about master and detail records and provide a method that allows you to get records related to the one you are working with. For example, starting from the row of the `Investor` table for "Nate Sun," you can navigate to the set of rows of the `Purchase` table describing his purchases.

A *cursor* is a database element that controls record navigation, the ability to update data, and the visibility of changes made to the database by other users. ADO.NET does not have an inherent cursor object, but instead includes data classes that provide the functionality of a traditional cursor. For example, the functionality of a forward-only, read-only cursor is available in the ADO.NET **DataReader** object. For more information about cursor functionality, see Data Access Technologies.

Minimized Open Connections

In ADO.NET you open connections only long enough to perform a database operation, such as a Select or Update. You can read rows into a dataset and then work with them without staying connected to the data source. In ADO the recordset can provide disconnected access, but ADO is designed primarily for connected access.

There is one significant difference between disconnected processing in ADO and ADO.NET. In ADO you communicate with the database by making calls to an OLE DB provider. In ADO.NET you communicate with the database through a data adapter (an OleDbDataAdapter, SqlDataAdapter, OdbcDataAdapter, or OracleDataAdapter object), which makes calls to an OLE DB provider or the APIs provided by the underlying data source. The important difference is that in ADO.NET the data adapter allows you to control how the changes to the dataset are transmitted to the database — by optimizing for performance, performing data validation checks, or adding any other extra processing.

> **Note** Data adapters, data connections, data commands, and data readers are the components that make up a .NET Framework data provider. Microsoft and third-party providers can make available other .NET Framework data providers that can be integrated into Visual Studio. For information on the different .NET Data providers, see .NET Data Providers.

Sharing Data Between Applications

Transmitting an ADO.NET dataset between applications is much easier than transmitting an ADO disconnected recordset. To transmit an ADO disconnected recordset from one component to another, you use COM marshalling. To transmit data in ADO.NET, you use a dataset, which can transmit an XML stream.

The transmission of XML files offers the following advantages over COM marshalling:

Richer data types

COM marshalling provides a limited set of data types — those defined by the COM standard. Because the transmission of datasets in ADO.NET is based on an XML format, there is no restriction on data types. Thus, the components sharing the dataset can use whatever rich set of data types they would ordinarily use.

Performance

Transmitting a large ADO recordset or a large ADO.NET dataset can consume network resources; as the amount of data grows, the stress placed on the network also rises. Both ADO and ADO.NET let you minimize which data is transmitted. But ADO.NET offers another performance advantage, in that ADO.NET does not require data-type conversions. ADO, which requires COM marshalling to transmit records sets among components, does require that ADO data types be converted to COM data types.

Penetrating Firewalls

A firewall can interfere with two components trying to transmit disconnected ADO recordsets. Remember, firewalls are typically configured to allow HTML text to pass, but to prevent system-level requests (such as COM marshalling) from passing.

Because components exchange ADO.NET datasets using XML, firewalls can allow datasets to pass.

Configuring Applications Using Dynamic Properties
Provides conceptual information about storing property values in a configuration file that can be changed at run time, which is particularly useful for connection information such as server name and user name.
Connection Pooling for the .Net Data Provider for SQL Server
Provides instructions on how to manually manage connection pooling if you are using the **SqlConnection** class.

Introduction to ADO.NET Connection Design Tools

To move data between a data store and your application, you must first have a connection to the data store.

> **Note** Data adapters, data connections, data commands, and data readers are the components that make up a .NET Framework data provider. Microsoft and third-party providers can make available other .NET Framework data providers that can be integrated into Visual Studio. For more information, see .NET Data Providers.

In ADO.NET you create and manage connections using connection objects:

- SqlConnection - an object that manages a connection to a SQL Server version 7.0 or later. It is optimized for use with SQL Server 7.0 or later by (among other things) bypassing the OLE DB layer.
- OleDbConnection - an object that manages a connection to any data store accessible via OLE DB.
- OdbcConnection - an object that manages a connection to a data source created by using a connection string or ODBC data source name (DSN).
- OracleConnection - an object that manages a connection to Oracle databases.

Connection Strings

All connection objects expose roughly the same members. However, the specific members available with a given **OleDbConnection** object depend on what data source it is connected to; not all data sources support all members of the **OleDbConnection** class.

The primary property associated with a connection object is the **ConnectionString** property, which consists of a string with attribute/value pairs for information required to log on to a database and point to a specific database. A typical **ConnectionString** property might look like the following:

```
Provider=SQLOLEDB.1;Data Source=MySQLServer;Initial Catalog=NORTHWIND;Integrated Security=SSP
I
```

This particular connection string specifies that the connection should use Windows integrated security (NT authentication). A connection string can instead include a user id and password, but this is not recommended, because these attributes are then compiled into your application and therefore a potential security breach. For more information, see Access Permissions for Web Applications and Security Model.

> **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

The most common attribute/value pairs used by OLE DB are also represented separately by an individual property, such as **DataSource** and **Database**. When working with a connection object, you can either set the **ConnectionString** property as a single string, or you can set individual connection properties. (If your data source requires connection-string values that are not represented by individual properties, then you must set the **ConnectionString** property.) Alternatively, you can also set the **ConnectionString** property to the path of a Microsoft Data Link (.udl) file. For more information about data link files, see Data Link API Overview.

> **Note** The **SQLConnection** object does not support — or allow you to specify — the **Provider** attribute.

Opening and Closing Connections

The two primary methods for connections are **Open** and **Close**. The **Open** method uses the information in the **ConnectionString** property to contact the data source and establish an open connection. The **Close** method shuts the connection down. Closing connections is essential, because most data sources support only a limited number of open connections, and open connections take up valuable system resources.

If you are working with data adapters or data commands, you do not have to explicitly open and close a connection. When you call a method of these objects (for example, the data adapter's **Fill** or **Update** method), the method checks whether the connection is already open. If not, the adapter opens the connection, performs its logic, and closes the connection again.

Methods such as **Fill** only open and close the connection automatically if it is not already open. If the connection is open, the methods use it but do not close it. This gives you the flexibility to open and close data commands yourself. You might do this if you have multiple data adapters that share a connection. In that case, it is inefficient to have each adapter open and close the connection when you call its **Fill** method. Instead, you can open the connection, call the **Fill** method of each adapter, and then

close the connection when you are done.

Pooling Connections

Applications often have different users performing the same type of database access. For example, in ASP.NET Web applications many users might be querying the same database to get the same data. In those cases, the performance of the application can be enhanced by having the application share, or "pool," connections to the data source. The overhead of having each user open and close a separate connection can otherwise have an adverse effect on application performance.

If you are using the **OleDbConnection**, **OdbcConnection**, or **OracleConnection** class, connection pooling is handled automatically by the provider, so you do not need to manage it yourself.

If you are using the **SqlConnection** class, connection pooling is managed implicitly, but also provides options that allow you to manage pooling yourself. For more information, see Connection Pooling for the .Net Framework Data Provider for SQL Server.

Transactions

Connection objects support transactions with a **BeginTransaction** method that creates a transaction object (for example, a SqlTransaction object). The transaction object in turn supports methods that allow you to commit or roll back the transactions.

Transactions are managed in code. For more information, see Performing Transactions.

Configurable Connection Properties

In many applications, connection information cannot be determined at design time. For example, in an application that will be distributed to many different customers, you might not be able to determine at design time the connection information (such as the name of a server).

Connection strings are therefore often specified as dynamic properties. Because dynamic properties are stored in a configuration file (and not compiled into the application binary files), they can be changed without having to recompile the application.

A typical strategy is to specify connection properties as dynamic properties, provide a way (such as a Windows Form or Web Form page) for users to specify the relevant details, and then update the configuration file. The dynamic-property mechanism built into the .NET Framework automatically gets the values from the configuration file when the property is read, and updates the file when the value is updated.

Connection Information and Security

Because opening a connection involves getting access to an important resource — a database — there are often security issues in configuring and working with a connection.

How you secure the application and its access to the data source depends on the architecture of your system. In a Web-based application, for example, users typically get anonymous access to Internet Information Services (IIS), and therefore do not provide security credentials. In that case, your application maintains its own logon information and uses it (rather than any specific user information) to open the connection and access the database.

> **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

The ASP.NET Web application binary files and configuration file are secured from Web access by the inherent ASP.NET security model, which prevents access to these files using any Internet protocol (HTTP, FTP, and so on). To prevent access to the Web server computer itself via other methods (for example, from within your internal network), you use the security features of Windows.

In intranet or two-tier applications, you can take advantage of the integrated security option provided by Windows, IIS, and SQL Server. In that model, a user's authentication credentials for the local network are also used to access database resources, and no explicit user name or password are used in the connection string. (Typically, permissions are established on the database server computer via groups, so that you do not need to establish individual permissions for every user who might access the database.) In this model, you do not need to store logon information for the connection at all, and there are no extra steps required to protect connection string information.

For more information about security, see the following topics:

- Best Practices for Securability
- .NET Framework Security
- Access Permissions for Web Applications

- ASP.NET Web Application Security

Design-Time Connections in Server Explorer

Server Explorer provides a way for you to create design-time connections to data sources. This permits you to browse available data sources; display information about the tables, columns, and other elements they contain; and edit and create database elements.

Your application does not directly use the connections you create this way. Generally, the information provided by a design-time connection is used to set properties for a new connection object that you add to your application.

For example, at design time you might use Server Explorer to create a connection to the SQL server MyServer and the database Northwind. Later, when designing a form, you can browse the Northwind database, select columns from a table, and drag them onto the form. This creates a data adapter for your form. It also creates a new form-specific connection, copying connection string information from the design-time connection to your new connection. When the application runs, your new connection is used to access the data source.

Information about design-time connections is stored on your local computer independently of a specific project or solution. Therefore, once you have established a design-time connection while working in an application, it appears in Server Explorer whenever you work in Visual Studio (as long as the server to which the connection points is available). For more information about using Server Explorer and creating design-time connections, see Adding New Data Connections in Server Explorer.

> **Note** The data connection you create in Server Explorer determines the objects that get created when dragging database elements onto a designer. For example, if you are connecting to a SQL Server at design time, and your data connection was originally set up by selecting the **OLE DB Provider for SQL Server**, then dragging a table from Server Explorer onto a designer will create a **SqlConnection** object. If your application requires an ODBC connection, be sure to select the **OLE DB Provider for ODBC** when creating your data connection in Server Explorer.

Connection Design Tools in Visual Studio

You usually do not need to directly create and manage connection objects in Visual Studio. When you use tools such as the Data Adapter Wizard, the tools typically prompt you for connection information (that is, connection-string information) and automatically create connection objects for you on the form or component you are working with.

However, if you want, you can add connection objects yourself to a form or component and set their properties. This is useful if you are not working with datasets (and therefore not with data adapters), but instead simply reading data. You might create connection objects yourself if you will be using transactions.

See Also

Creating ADO.NET Connection Objects | Connecting to a Data Source Using ADO.NET |
Connection Pooling for the .NET Framework Data Provider for SQL Server

Creating ADO.NET Connection Objects

If you are using data design tools in Visual Studio, you often do not need to explicitly create a connection object for your form or component. However, in some instances you might find it convenient to create a connection alone.

Your options for creating a connection are:

- Use any of the following data design tools, which create a connection object as part of the task they are performing:
  - Data Adapter Configuration Wizard - this wizard prompts you for information to create a connection that is in turn linked to a data adapter. For more information, see Data Adapter Configuration Wizard.
  - Data Form Wizard - this wizard creates the connection object as part of the form it is configuring. For more information, see Data Form Wizard.
- Drag a table, selection of columns, or stored procedure from Server Explorer onto a form or component. By dragging one of these elements onto a form, you create both a data adapter and a connection. For more information, see Adding New Data Connections in Server Explorer.
- Create a standalone connection. This option creates a connection object on your form or component whose properties you configure manually. This strategy is useful if you intend to set connection properties at run time or if you simply prefer setting the properties in the Properties window. The procedure is described below.
- Create a connection programmatically. For more information about creating and managing connections in code, see Connecting to SQL Server Using ADO.NET and Connecting to an OLE DB Data Source Using ADO.NET.

To create a connection

1. From the **Data** tab of the Toolbox, drag a connection object onto your form or component. For more information about which connection object to use, see Introduction to ADO.NET Connection Design Tools.
2. Select the connection in the designer and then use the **Properties** window to set its connection string.

   - You can set the **ConnectionString** property as a single unit. (You cannot specify a **Provider** attribute for a **SqlConnection** object.)

     – or –

   - You can set individual properties (**DataSource**, **Database**, **UserName**, and so on). If you set individual properties, the connection string is built for you.

     > **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

3. If you want to rename the connection object, set its **Name** property.

   > **Note** If connection information needs to be set at run time, you can configure connection properties as dynamic properties. For more information, see Configuring Applications Using Dynamic Properties.

4. If you want to set properties at run time without recompiling the application, specify connection properties. For more information about making connection properties dynamic, see Introduction to ADO.NET Connection Design Tools. For an overview of dynamic properties, see Configuring Applications Using Dynamic Properties.

Creating Connection to SQL Servers | Creating Connections to Access Databases | Creating Connections to ODBC Data Sources | Creating Connections to Oracle Databases | Introduction to ADO.NET Connection Design Tools | Connecting to a Data Source Using ADO.NET | Connection Pooling for the .NET Data Provider for SQL Server

Creating Connections to SQL Server

When connecting to SQL Server use the **Microsoft OLE DB Provider for SQL Server**.

> **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

There are two ways to connect to SQL Server:

- Visually, with design-time tools.
- Programmatically.

Connecting to SQL Server in Server Explorer

Establishing a connection to SQL Server in Server Explorer allows you to easily create SqlConnection, SqlDataAdapter, and SqlCommand objects by dragging data objects from Server Explorer onto forms or designers.

To create a connection in Server Explorer

1. In Server Explorer, right-click **Data Connections** and click **Add Connection**.

   The **Data Link Properties** dialog box opens.

2. The default provider is **Microsoft OLE DB Provider for SQL Server**.
3. Select a server name from the drop-down list, or type the location of the server where the database you want to access is located.

   > **Note** Selecting the database on the server is a separate action. Refresh the list by clicking **Refresh**.

4. Based on the requirements of your database or application, select either Windows NT Integrated security or use a specific user name and password to log on to the SQL Server. For more information, see Data Link Properties Dialog Box.
5. Select the database you want to connect to from the drop-down list.
6. Click **OK**.

Connecting to SQL Server from within your application

Creating connections to data sources from within your application can be accomplished visually using Visual Studio .NET designers, or programmatically by creating data connection objects in code.

Connecting to SQL Server Visually

Visual Studio supports creating data objects by dragging items from Server Explorer or the Data tab of the Toolbox onto your form or designer.

To create a connection from Server Explorer

1. Create a **Data Connection** in Server Explorer to your SQL Server. For more information, see the above section titled "Connecting to SQL Server in Server Explorer."
2. Drag the connection onto your form or designer.

   A **SqlConnection** object appears in the component tray.

3. Advance to the section "Next Steps" later in this topic.

To create a connection from the Data tab of the Toolbox

1. Drag a **SqlConnection** onto your form or designer.

   An unconfigured **SqlConnection** object appears in the component tray.

2. In the Properties window, click the **ConnectionString** property.
3. Select an existing connection in the drop-down list, or click **New Connection** to open the Data Link Properties Dialog Box and configure a new connection.
4. Advance to the section "Next Steps" later in this topic.

Connecting to SQL Server Programmatically

You can create a **SqlConnection** object directly in code.

To programmatically create a connection between your application and a SQL Server database

- The following code creates a SqlConnection object, sets the SqlConnection.ConnectionString property, and opens the connection.

```
' Visual Basic
Public Sub ConnectToSql()
    Dim conn As New SqlClient.SqlConnection
    ' TODO: Modify the connection string and include any
    ' additional required properties for your database.
    conn.ConnectionString = & _
    "integrated security=SSPI;data source=SQL Server Name;" & _
    "persist security info=False;initial catalog=northwind"
    Try
        conn.Open()
        ' Insert code to process data.
    Catch ex As Exception
        MessageBox.Show("Failed to connect to data source")
    Finally
        conn.Close()
    End Try
End Sub

// C#
public void ConnectToSql ()
{
    System.Data.SqlClient.SqlConnection conn =
        new System.Data.SqlClient.SqlConnection ();
    // TODO: Modify the connection string and include any
    // additional required properties for your database.
    conn.ConnectionString =
     "integrated security=SSPI;data source=SQL Server Name;" +
     "persist security info=False;initial catalog=northwind";
    try
    {
        conn.Open();
        // Insert code to process data.
    }
        catch (Exception ex)
    {
        MessageBox.Show("Failed to connect to data source");
    }
    finally
    {
        conn.Close();
    }
}
```

Next Steps

Now that you have established a connection between your application and the SQL Server database, you can create objects to fetch and update data. The following table provides links to some relevant topics.

To	See
Fetch read-only data	Retrieving Data Using the DataReader
Fill a dataset with data	ADO.NET Datasets

Execute SQL statements directly	Performing Database Operations Directly

Creating Connections to Access Databases

When connecting to an Access database, use the **Microsoft Jet 4.0 OLE DB Provider**.

> **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

There are two ways to connect to an Access database:

- Visually, with design-time tools.
- Programmatically.

Connecting to an Access Database in Server Explorer

Establishing a connection to an Access database in Server Explorer allows you to easily create OleDbConnection, OleDbDataAdapter, and OleDbCommand objects by dragging data objects from Server Explorer onto forms or designers.

To create a connection in Server Explorer

1. In Server Explorer, right-click **Data Connections** and click **Add Connection**.
2. In the **Data Link Properties** dialog box, click the **Provider** tab.
3. Click the **Microsoft Jet 4.0 OLE DB Provider**, then click **Next**.
4. Click the ellipsis (...) button to browse to the Microsoft Access (.mdb) file you want to access.
5. Type the **User ID** to use for authentication when you log on to the data source.
6. Type the **Password** to use for authentication when you log on to the data source.
7. Click **OK**.

Connecting to an Access Database from Within Your Application

Creating connections to data sources from within your application can be accomplished visually using Visual Studio .NET design-time tools (including Server Explorer and the Toolbox), or programmatically by creating data connection objects in code.

Connecting to an Access Database Visually

Visual Studio supports creating data objects by dragging items from Server Explorer or the Data tab of the Toolbox onto your form or designer.

To create a connection from Server Explorer

1. Create a **Data Connection** in Server Explorer to your Access database. For more information, see the above section titled "Connecting to an Access database in Server Explorer."
2. Drag the connection from Server Explorer onto your form or designer.

   An **OleDbConnection** object appears in the component tray.

3. Advance to the section "Next Steps" later in this topic.

To create a connection from the Data tab of the Toolbox

1. Drag an **OleDbConnection** object onto your form or designer.

   An unconfigured **OleDbConnection** object appears in the component tray.

2. In the Properties window, click the **ConnectionString** property.
3. Do one of the following:

   - Click an existing connection in the drop-down list.

     - or -

   - Click **New Connection** to open the Data Link Properties Dialog Box and configure a new connection.

4. Advance to the section "Next Steps" later in this topic.

Connecting to an Access Database Programmatically

You can create a **OleDbConnection** object directly in code.

To programmatically create a connection between your application and an Access database

- The following code creates an OleDbConnection object, sets the OleDbConnection.ConnectionString property, and opens the connection.

```
' Visual Basic
Public Sub ConnectToAccess()
    Dim conn As New System.Data.OleDb.OleDbConnection()
    ' TODO: Modify the connection string and include any
    ' additional required properties for your database.
    conn.ConnectionString = & _
    "Provider=Microsoft.Jet.OLEDB.4.0;Data source=" & _
    "C:\Documents and Settings\username\My Documents\dbFile.mdb"
    Try
       conn.Open()
       ' Insert code to process data.
    Catch ex As Exception
       MessageBox.Show("Failed to connect to data source")
    Finally
       conn.Close()
    End Try
End Sub

// C#
public void ConnectToAccess()
{
    System.Data.OleDb.OleDbConnection conn = new
        System.Data.OleDb.OleDbConnection();
    // TODO: Modify the connection string and include any
    // additional required properties for your database.
    conn.ConnectionString = @"Provider=Microsoft.Jet.OLEDB.4.0;" +
        @"Data source= C:\Documents and Settings\username\" +
        @"My Documents\AccessFile.mdb";
    try
    {
        conn.Open();
        // Insert code to process data.
    }
        catch (Exception ex)
    {
        MessageBox.Show("Failed to connect to data source");
    }
    finally
    {
        conn.Close();
    }
}
```

Next Steps

Now that you have established a connection between your application and the Access database, you can create objects to fetch and update data. The following table provides links to some relevant topics.

To	See
Fetch read-only data	Retrieving Data Using the DataReader
Fill a dataset with data	ADO.NET Datasets

Execute SQL statements directly	Performing Database Operations Directly

Creating Connections to ODBC Data Sources

When connecting to a DSN, use the **Microsoft OLE DB Provider for ODBC Drivers**.

> **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

There are two ways to connect to an ODBC data source:

- Visually, with design-time tools.
- Programmatically.

Connecting to an ODBC Data Source in Server Explorer

Establishing a connection to an ODBC data source in Server Explorer allows you to easily create OdbcConnection, OdbcDataAdapter, and OdbcCommand objects by dragging data objects from Server Explorer onto forms or designers.

To create a connection in Server Explorer

1. In Server Explorer, right-click **Data Connections** and click **Add Connection**.
2. In the **Data Link Properties** dialog box, click the **Provider** tab.
3. Click the **Microsoft OLE DB Provider for ODBC Drivers**, then click **Next**.
4. Select from the list, or type the ODBC data source name you want to access.
5. Type the **User ID** to use for authentication when you log on to the data source.
6. Type the **Password** to use for authentication when you log on to the data source.
7. Click **OK**.

Connecting to an ODBC Data Source from Within Your Application

Creating connections to data sources from within your application can be accomplished visually using Visual Studio .NET designers, or programmatically by creating data connection objects in code.

Connecting to an ODBC Data Source Visually

Visual Studio supports creating data objects by dragging items from Server Explorer or the Data tab of the Toolbox onto your form or designer.

To create a connection from Server Explorer

1. Create a **Data Connection** in Server Explorer to your ODBC data source. For details, see the above section titled "Connecting to an ODBC data source in Server Explorer."
2. Drag the connection onto your form or designer.
3. An **OdbcConnection** object appears in the component tray.
4. Advance to the section "Next Steps" later in this topic.

To create a connection from the Data tab of the Toolbox

1. Drag an **OdbcConnection** onto your form or designer.

   An unconfigured **OdbcConnection** object appears in the component tray.
2. In the Properties window, click the **ConnectionString** property.
3. Select an existing connection in the drop-down list or click **New Connection** to open the Data Link Properties Dialog Box and configure a new connection.
4. Advance to the section "Next Steps" later in this topic.

Connecting to an ODBC Data Source Programmatically

You can create an **OdbcConnection** object directly in code.

To programmatically create a connection between your application and a DSN

- The following code creates an OdbcConnection object, sets the OdbcConnection.ConnectionString property, and opens the connection.

```
' Visual Basic
    Public Sub ConnectToOdbc()
        Dim conn As New System.Data.Odbc.OdbcConnection
        ' TODO: Modify the connection string and include any
        ' additional required properties for your database.
        conn.ConnectionString = & _
            "FIL=MS Access;DSN=valid data source name"
        Try
            conn.Open()
            ' Insert code to process data.
        Catch ex As Exception
            MessageBox.Show("Failed to connect to data source")
        Finally
            conn.Close()
        End Try
    End Sub

// C#
public void ConnectToData()
{
    System.Data.Odbc.OdbcConnection conn =
        new System.Data.Odbc.OdbcConnection ();
    // TODO: Modify the connection string and include any
    // additional required properties for your database.
    conn.ConnectionString = "FIL=MS Access;DSN=valid data source name";
    try
    {
        conn.Open();
        // Process data here.
    }
    catch (Exception ex)
    {
        MessageBox.Show("Failed to connect to data source");
    }
    finally
    {
        conn.Close();
    }
}
```

Next Steps

Now that you have established a connection between your application and an ODBC data source, you can create objects to fetch and update data. The following table provides links to some relevant topics.

To	See
Fetch read-only data	Retrieving Data Using the DataReader
Fill a dataset with data	ADO.NET Datasets
Execute SQL statements directly	Performing Database Operations Directly

Creating Connections to Oracle Databases

When connecting to an Oracle database use the **Microsoft OLE DB Provider for Oracle**.

> **Note** To enable drag and drop support from **Server Explorer** for Oracle databases, the data connection must use the Microsoft OLE DB Provider for Oracle.
>
> **Security Note** Storing connection-string details (such as the server name, user name, and password) can have implications for the security of your application. Using Windows Integrated Security is a more secure way to control access to a database. For more information, see Database Security.

There are two ways to connect to an Oracle database:

- Visually, with design-time tools.
- Programmatically.

Connecting to an Oracle Database in Server Explorer

To create a connection in Server Explorer

1. In Server Explorer, right-click **Data Connections** and click **Add Connection**.
2. In the **Data Link Properties** dialog box, click the **Provider** tab.
3. Click the **Microsoft OLE DB Provider for Oracle**, then click **Next**.
4. Type the server where the database you want to access is located.
5. Type the password to use for authentication when you log on to the data source.
6. Click **OK**.

Connecting to an Oracle Database from within your application

Creating connections to data sources from within your application can be accomplished visually using Visual Studio .NET designers, or programmatically by creating data connection objects in code.

Connecting to an Oracle Database Visually

Visual Studio supports creating data objects by dragging items from Server Explorer or the Data tab of the Toolbox onto your form or designer.

To create a connection from Server Explorer

1. Create a **Data Connection** in Server Explorer to your Oracle database. For more information, see the above section titled "Connecting to an Oracle database in Server Explorer."
2. Drag the connection onto your form or designer.
3. An **OracleConnection** object appears in the component tray.
4. Advance to the section "Next Steps" later in this topic.

To create a connection from the Data tab of the Toolbox

1. Drag an **OracleConnection** onto your form or designer.

   An unconfigured **OracleConnection** object appears in the component tray.

2. In the Properties window, click the **ConnectionString** property.
3. Select an existing connection in the drop-down list, or click **New Connection** to open the Data Link Properties Dialog Box and configure a new connection.
4. Advance to the section "Next Steps" later in this topic.

Connecting to an Oracle Database Programmatically

You can create an **OracleConnection** object directly in code.

To programmatically create a connection between your application and an Oracle database

- The following code creates an OracleConnection object and sets the OracleConnection.ConnectionString property.

```
' Visual Basic
Public Sub ConnectToOracle()
    Dim conn As New OracleClient.OracleConnection()
    ' TODO: Modify the connection string and include any
    ' additional required properties for your database.
    conn.ConnectionString = & _
    "Data Source=<oracle data source name>;Integrated Security=yes"
    Try
        conn.Open()
        ' Insert code to process data.
    Catch ex As Exception
        MessageBox.Show("Failed to connect to data source")
    Finally
        conn.Close()
    End Try
End Sub

// C#
public void ConnectToOracle()
{
    OracleClient.OracleConnection conn =
        new OracleClient.OracleConnection ();
    // TODO: Modify the connection string and include any
    // additional required properties for your database.
    conn.ConnectionString = "Data Source=" +
        "<oracle data source name>;Integrated Security=yes";
    try
    {
        conn.Open();
        // Insert code to process data.
    }
        catch (Exception ex)
    {
        MessageBox.Show("Failed to connect to data source");
    }
    finally
    {
        conn.Close();
    }
}
```

Next Steps

Now that you have established a connection between your application and an Oracle database, you can create objects to fetch and update data. The following table provides links to some relevant topics.

To	See
Fetch read-only data	Retrieving Data Using the DataReader
Fill a dataset with data	ADO.NET Datasets

ADO.NET Data Adapters

The following topics provide information about ADO.NET data-adapter objects and how to work with them in Visual Studio. Adapters are used to exchange data between a data source and a dataset.

In This Section

Introduction to Data Adapters
Provides an overview of what data adapters are, what they are used for, and how they are structured.
Parameters in Data-Adapter Commands
Describes the structure and use of parameters that adapters pass at run time to SQL statements or stored procedures.
Table Mapping in Data Adapters
Describes options for how to map column names between a source table and a dataset table.
Creating Data Adapters
Lists different ways of creating data adapters in Visual Studio.
Configuring Parameters for Data Adapters
